In the early cases there is usually no shadow cast on the plate or fluoroscope. This is natural enough, considering the nature of the pathological anatomy of the disease at this period. Various other changes have, however, been observed. First, there is the fact that when the patient takes a deep breath the apices do not light up to the extent that they do in health. In health there is a very evident difference in transillumination between inspiration and expiration, inspiration giving a brighter appearance. Secondly, it has been pointed out that on the affected side the diaphragm does not move through so wide a space. The heart of tuberculosis is present in the early as well as the late cases. It is a small heart, hanging vertically in the chest and close to the midline. Again, a calcification of the costal cartilages has been made out, and also the tracings of the hilus shadows are of significance in these cases.

In considering the general usefulness of radiography in phthisis, then, it must be evident that it is just in the cases in which we need it the least that it gives us the most data—in the late and moderately advanced cases. It is in these cases that the diagnosis by means of physical diagnosis, sputum examination, temperature chart, etc., is in most cases quite satisfactory. In the early cases the diagnosis is usually one of great difficulty by the above mentioned methods. It is, too, most perplexing. Judgment is
here, if anywhere, difficult, and "experience fallacious." And as it is only in these cases that any sure prospect of cure can be held out, the importance of the diagnosis is proportionately great. The difficulty lies in this: That the gross anatomical changes in the lungs are so few as to give very slight physical signs, and those indefinite. That the x ray would reveal nothing tangible under these circumstances is perfectly reasonable. Those signs such as diminished translucency of the apices, fixity of the diaphragm, tuberculous type of heart, etc., are open to the same objection as such physical signs as Kronig's method of percussion and Phillips's tidal percussion. The objection is that in any given case it is almost impossible to say whether any one sign is of pathological significance or whether it is a deviation within the limits of the normal. The x ray should always be used in obscure causes when the possibility of early pulmonary tuberculosis is under discussion. It is the accumulation of either positive or negative evidence which counts. The diagnosis is not of equal difficulty in all cases. One single symptom or sign may throw the balance, and it is always possible that the radiological examination may furnish that last straw. Its negative evidence, too, is very comforting when we can find nothing by physical examination of the chest. The point that we wish to emphasize, however, is that the x ray is, in early phthisis, a means of diagnosis that is of use only in conjunction with the other methods employed. It does not assume the central importance that it assumes in kidney stone, for instance, or aortic aneurysm. A careful history, a temperature chart, pulse, blood pressure, and weight charts, physical examination of the chest, examination of the sputum, tuberculin reaction, and the fluoroscopic examination—these are the combined means which we must use, and, on the whole in our judgment, the last two are of the least importance.

We have just mentioned the value of the x ray as negative evidence. In a certain group of cases this negative evidence rises to extreme importance. In a paper before the International Congress on Tuberculosis in 1908 Reynier reported eighteen cases of asthma which, in spite of the popular impression that asthmatics are relatively immune to tuberculosis, turned out to be early phthisis. Keeping this suggestion in mind, we have in the past few years found one case of bronchial asthma in which tubercle bacilli were demonstrated in the sputum. With this experience, we have naturally regarded many cases of asthma in young individuals with some suspicion. The difficulty of determining anything in them by auscultation is apparent, and the fluoroscope is here of prime importance. One such case, by way of illustration, was of a young man twenty-three years of age who presented himself at the outpatient department of the University of Kansas for attacks of wheezing, continuous expectoration of small amounts, and a gradual loss of weight of from ten to twelve pounds, extending over a period of six months. His attacks were typical attacks of bronchial asthma. But the loss of weight, the low blood pressure (from 108 to 112 mm. Hg, persisting over several examinations) temperatures of 97.4° F. and 99° F., a pulse of from 90 to 96, and his thin and anemic appearance aroused suspicion. Percussion was negative, and auscultation was sometimes negative and sometimes obscured by dry râles of various grades of intensity. The fluo-
roscopic examination of his chest showed no shadows, no enlarged hilus glands, and quite fair illumination of the apices on deep inspiration. In this case I regarded the negative fluoroscopic data decisive.

In connection with asthma, too, we have the records of one case of fascinating interest. In brief, the patient was a male negro, aged thirty-six, who presented himself at the outpatient dispensary of the University of Kansas, first on February 17, 1910, with extreme dyspnea, ascites, enormously enlarged liver, and evidences of fluid in the right chest; the heart and kidneys presented no evidence of disease. Our first diagnosis was cirrhosis of the liver, and the abdomen and right chest were repeatedly tapped. In the face of a history of syphilis of six years' duration and a positive Wassermann reaction we tentatively tried him on mercury and iodide of potassium. The liver began to recede and tappings became only necessary at increasingly infrequent intervals, and by the last of May he had been free of fluid for some weeks. The liver had receded somewhat, but was still down to within three fingers of the umbilicus; he went to work and we lost sight of him. He reappeared December 11, 1911, having been well up to within a week before. Since then he had had great dyspnea and wheezing spells. On examination we found sonorous and sibilant râles, almost entirely confined to the left lung. The x-ray examination showed a large shadow near the left primary bronchus. With salvarsan, mercury, and iodide of potassium, his symptoms were relieved, and six weeks afterward another fluoroscopic examination showed the previous shadow to have diminished very greatly in size. We have concluded that the shadow seen on the picture was a mass of enlarged syphilitic lymph glands which compressed the left bronchus. We cannot leave this part of the subject without remarking that, from a very limited experience, in the enlarged bronchial lymph glands in children causing dyspnea, stridor, brassy cough, etc., the x-ray is the only reliable diagnostic agent.

Pleural effusion casts a shadow on the fluoroscopic screen. The valuable studies of Englebach and Carmen (8) have taught us some highly important lessons in the pathological anatomy of the condition. But in ordinary clinical routine the use of radiography is not warranted, as diagnosis by simpler and easier means is thoroughly satisfactory. This is true also of hydrothorax. With new growths of the lung and tumors of the mediastinum we have had no experience. Many cases are, however, on record in which the ray revealed the condition present. In lung abscess it is of first rate importance. We have recently had a case, the plate of which is here represented in Fig. 5. The patient was a man forty years of age who presented himself with an afternoon fever and profuse expectoration which dated from pneumonia six years before; he had had several pulmonary hemorrhages and had lost twenty pounds in weight in a year. Physical examination revealed crepitant râles and dullness confined to the lower part of the right chest. The use of the x-ray in empyema is an interesting question. We have come to formulate our procedure thus: In every case of continued fever after the crisis of a lobal pneumonia, where the diagnosis of pus in the pleural sac is not readily established, a radiograph should be taken. This will show the cases of interlobular empyema, obscure lung abscess, and delayed resolution.

CABOT'S recent dictum that unresolved pneumonia usually means empyema is perfectly true. The objection to such a statement is that in the course of time one comes to think of it as meaning that unresolved pneumonia does not exist. This is distinctly not true. Cases have been found at autopsy and their pathological history described (10). The plate in a case in which the x-ray proved its value is reproduced in Fig. 6. The patient was a man thirty-three years of age. On April 27, 1912, he had a chill, the advent of a lobar pneumonia. On May 4 his temperature fell to 96° F., the pulse and respirations came down, and he was considered to have passed his crisis. Four days later he began to have an afternoon temperature and sweets. From May 9th to 14th his temperature reached 102° F., or thereabouts, in the afternoon, and was between 99° and 100° F. in the morning. He did not cough. Dr. H. P. Kuhn visited him at his home in Plainsville, Kansas, found dullness in the left chest behind, and made an exploratory aspiration several times with-
tually drains the organ, being in the great majority of cases, only a very little higher than the lowest point of the stomach; the upper pole is always occupied by an air space known as the "Magen-blase." As food enters the stomach it does not, as one would expect, sink into the lowest part of the sac. The stomach wall muscle has a definite tone, and normally maintains the food mass in a vertical column. Fig. 7 is a diagram copied from Holzknecht (11) of the normal types of gastric form toxicity with the rate at which the food leaves the stomach expressed in hours. As soon as the food enters the stomach peristalsis begins, and waves can be easily seen on the greater and lesser curvatures moving pylorusward until a bolus of food is separated from the larger mass and expressed into the duodenum.

In the stomach and intestines the X ray as a means of diagnosis comes fully into its own. In a single examination we learn:
1. The shape and size of the stomach.
2. The tone of the gastric muscle.
3. The emptying rate of the stomach, whether there is stasis or not.
4. Whether there is any growth into the lumen of the stomach carcinoma.
5. Whether or not there is any constriction of the lumen hour glass stomach.

These things can be learned by no other method—
even exploratory laparotomy will not tell us anything about the first three. They are easily obtained, without a tithe of the difficulty of gastric lavage. And they are the very core of the objective facts we wish to know about the stomach for diagnosis.

GASTRIC ULCER.

As with pulmonary tuberculosis, we must distinguish between early and late cases. In the cases of early simple gastric ulcer the Röntgen ray is merely an adjunct to the well taken clinical history. The anatomical changes and changes in the movements and emptying rate of the stomach are not notable at this stage. The standing of the ray does not suffer as much, however, in this condition as in phthisis, as the diagnosis by means of the history, the physical examination, and the chemical examination of the gastric contents is relatively satisfactory. In chronic ulcer causing stenosis of the pylorus the fluoroscope will demonstrate the stenosis and rise in importance in the individual case in direct proportion to the difficulty encountered in diagnosis otherwise. In perforating gastric ulcer with diverticula formation in the liver and lesser peritoneum Haudek (12) has described the picture which he regards as diagnostic. With it I have had no experience. I have had little radiological experience either with duodenal ulcer or the duodenal dilatation described by Jordan (13). In several cases of what we may call dyspepsia (meaning by that an alimentary disturbance in which we were able to rule out ulcer and cancer, appendicitis, gallstones, nephritis, high blood pressure, pregnancy, etc.), the patients were submitted to X ray examination, often with great benefit to an understanding of the case. Gastritis and enteritis have been found in this way. In two cases the tone of the gastric musculature seemed diminished.

(To be continued.)

CONCERNING THE ETIOLOGY OF HYPERPOTROPHIC PULMONARY OSTEOARTHROPATHY.

With a Report of Five Additional Cases.

By Harlow Brooks, M. D.,
New York,
Professor of Clinical Medicine, University of Bellevue Hospital Medical College.

(Closed from page 674.)

Family History: Father, aged forty-two years; mother, aged forty-three years; three brothers and one sister all alive and well. Parents were first cousins. No tuberculosis or other familial disease present.

Personal History: The patient was the sixth child; birth normal. One hour after its birth mother noticed that the child breathed with difficulty, that respirations were apparently dyspneic and noisy. The attending physician stated at this time that the child had some congenital pulmonary affection. She was breast fed, but did not nurse readily and always coughed and often vomited after nursing. She slept badly and breathing continued to be peculiar. She had pneumonia three times, the first at one half year, the second one month later, and a third attack two weeks later (?). After these pulmonary attacks the mother noticed that the child was frequently blue and that her cough and breathing were worse. Aside from these attacks the child had no disease during early infancy. She walked at twenty months of age, and began to talk at about the same time. The first tooth appeared at the close of her first year; subsequent history of dentition was uneventful. She is married; has a younger brother and a younger sister; the younger sister had frequent attacks of coughing, especially at night. Up to last winter she was apparently getting worse in so far as the respirations were concerned; and dyspnea and cough were continuously present, and she expectedorated very freely after her coughing paroxysms. She complained of pain in the sides of the thorax, and last winter began to have "spells" which consisted of severe dyspnea, cough, and cyanosis, especially of the face. Had had these attacks about twice monthly. The child was always worse during the winter season. She lost several pounds in weight last winter, but gained while in the country during the past summer. The mother first noticed that the child's fingers and toes began to take on their present peculiar shape about three years ago. Last winter, from no apparent cause, the fingers became much swollen and the nails began to ooze blood along the bases of the nails; this hemorrhage would continue off and on for weeks at a time. Chief complaints: Dyspnea, cough, and expectoration; pain in the extremities.

Physical Status: The patient is a well nourished but undersized child. There are no gross skeletal deformities, and the panniculus adiposus and the skeletal musculature are well developed. Skin warm, soft, and moist; well nourished; no eruptions or scars present. The mucous membranes are deeply colored from a pronounced cyanosis. The head is rather large and broad, with a tendency toward the cubical type and with marked protrusion of the forehead and malar prominence. There is a flattening of the nasal bridge and the tip of the nose is cyanotic and bulbous in shape; the face is full and "bloated," especially the cheeks and lips, which are quite cyanotic, while the whole cast of the countenance, with the narrowed eyes, slitted, and the mongolian type, or, as expressed by a member of the house staff, like that of a "miniature squaw." Dyspnea is apparent, even when she is at rest, from the movements of the alae nasi and from the thoracic movements and posture. These become exaggerated on exercise. Vision good, and ocular movements normal; pupils are equal and normal in their reactions; conjunctiva of good color. The tongue is rather large, flabby, and somewhat cyanosed. The teeth are fair condition, a few are missing and the insertion of mucous membrane is ulcerated in a few instances; mucous membrane of hard and soft palate and of pharynx is moderately cyanotic. The vessels of the neck show moderate pulsations. No lymph nodes in the neck are palpable; the thyroid is not readily palpable, and the neck is short
and stumpy; no thymus dullness or shadow can be made out. The thorax is definitely of the rachitic and pigeon breast type; left side more prominent than the right, which is smaller and depressed anteriorly. There is a marked left shoulder drop, some dorsal scoliosis, and the scapulae are prominent; no clavicular depressions. Respiration are labored and stertorous. There is visible retraction in the clavicular and suprasternal fossae and audible respiratory grunt, and the expansion on both sides is markedly deficient. On percussion, a general boardy quality throughout, with a small area of dullness at right base posteriorly; Abrupt response to deep grunting respiration with scapular rhonchi, sibilant, sonorous, and crepitant rales throughout.

These latter are especially numerous over left base, front and back; inspiration is short and expiration prolonged, averaging sixty a minute. The area of cardiac dullness is uniformly enlarged; and heart-visible and his-palpable in fifth interspace, 2½ inches from the median line. Right border lies 1½ inches beyond the mid sternal line; left border just outside the nipple line. The heart action is regular, rapid; the sounds at apex and aortic areas are naturally, to the perception of the thorax on the right out, even after exercise, which seems to be well borne in so far as the heart action is concerned. The left pulse is apparently stronger than the right, rate 120 a minute, and no other abnormalities are apparent. Abdomen rigid, not tender or distended, subcostal dullness; some hepatic dullness, not palpable; liver dullness extends one finger's breadth below costal margin, but because of the abdominal rigidity the liver cannot be palpated; spleen and kidneys not palpable. There is marked clubbing of the finger nails and subcostal pulsation; some abdominal, but not severe palpation, but none in the wrists or ankles, which, from palpation, appear to be enlarged and roughened. The finger and toe nails are much thickened and sharply curved. No edema, although the appearance of the abdomen is-masked, as far as the extremities are concerned. The neurological status was reported as normal by the attending neurologist, Doctor Abrahamson. The child was found to be mentally bright, easily taught, and suggestive; no abnormality save dullness and impaired mobility of the right shoulder. The pulse is generally rapid, 120 to 130, and after exercise, no increase. The respiration is deep and regular, from 20 to 25 breaths per minute, and the movements of the chest are not perceptible. The child was taken to a hospital, where the following examination was made:

**Previous History:** A child he was frail, he contracted and suffered from bronchitis and tuberculosis, but not by any means the severe type. He was now in his fifth year, suffering from chronic asbestosis and subacute pneumonia, with some suggestion of tuberculosis, though at no time were tubercle bacilli detected in the sputum. At the age of three and one-half years the patient suffered from a severe attack of bilateral lobar pneumonia, from which he made a slow recovery; at the age of five and one-half, tuberculosis being suspected, he was sent West, where he embarked upon a ranching venture in Wyoming, under the conditions of life there, though subject to privations and exposures to the elements, he was apparently well. As he reached the abnormal temperature, the cough subsided, and he found himself able to do a "man's work" as a cowboy. The life was extremely congenial to him, and this may in part account for some of the benefit derived from it. Later evidence throughout the season showed that, as a volunteer cavalry troop, and though the service was almost constantly in the tropics, he was able to stand the work well, and was returned to his home station in fairly good condition. Social and business obligations recalled him to New York, where he has lived the life of ease. The frequent attacks of bronchitis, manifested by fever, persistent productive cough, and loss of strength and weight. The patient had at times indulged unwisely in both alcohol and tobacco. He had taken drink practically only on rare social occasions, but smoked a pipe, and never suffered from any venereal infection and had lived a moderate sexual life.

**Present History:** October 23, 1912. The patient came to me having contracted a recent "cold," which had manifested itself by cough and expectoration and pain in the chest, particularly over the upper lobe of right lung. The appetite was poor, he was constipated and weak, and slight alterations in temperature caused him to sneeze and to experience chilly sensations at night. The face is somewhat congested; skin thin and turbid; malar bones very prominent, tender on deep pressure, and the end of the nose is typically globular. Frontal alopecia is marked and rapidly progressive. The features are coarse. The face is somewhat thickened, considerably flattened above, immobile. Aside from moderate carination the examination of abdomen is negative. Ankle and wrists markedly enlarged and thickened, roughness and tenderness of the peristeum is apparent on firm palpation. The heart is small, and not left, but apparently not enlarged; the muscle tone is poor, but no murmurs can be elicited, even after exercise which gives rise to considerable dyspnea. The retrosternal dullness at the base is not increased; no tracheal tug or other evidence of aneurysm, aortitis, or mitral stenosis. Examination of the lungs shows areas of diminished resonance associated with increased vocal and tactile fremitus at the apices on both sides and over the entire base on the right; the breath sounds are harsh and coarse on the right. The thorax is long, barrel shaped, considerably flattened above, immobile.

**Diagnosis:** Chronic bronchitis and bronchopneumonia, with probably pulmonary fibrosis; displaced and dilated heart (well compensated); hypertrophic pulmonary osteoarthropathy. The child remained three months in the hospital, and is still under occasional observation. During this period she made considerable progress as regards relief of the pulmonary conditions, but without apparent improvement of the bone lesions. She progressed rapidly under the insulin and diet; the original observation of her case convinced us that the original assumption of a cretinoid condition was incorrect.

**Case IV.** Mr. T. A. E., seen in consultation with Dr. E. D. Male, aged fifty-one years, descended from an ancestry distinguished for both physical and mental vigor. Family history negative as to all systemic or hereditary taints.

The retrosternal dullness at the base is not increased; no tracheal tug or other evidence of aneurysm, aortitis, or mitral stenosis. Examination of the lungs shows areas of diminished resonance associated with increased vocal and tactile fremitus at the apices on both sides and over the entire base on the right; the breath sounds are harsh and coarse on the right. The thorax is long, barrel shaped, considerably flattened above, immobile.

**Diagnosis:** Chronic bronchitis and bronchopneumonia, with probably pulmonary fibrosis; displaced and dilated heart (well compensated); hypertrophic pulmonary osteoarthropathy. The child remained three months in the hospital, and is still under occasional observation. During this period she made considerable progress as regards relief of the pulmonary conditions, but without apparent improvement of the bone lesions. She progressed rapidly under the insulin and diet; the original observation of her case convinced us that the original assumption of a cretinoid condition was incorrect.

**Case IV.** Mr. T. A. E., seen in consultation with Dr. E. D. Male, aged fifty-one years, descended from an ancestry distinguished for both physical and mental vigor. Family history negative as to all systemic or hereditary taints.
fetid odor; contains numerous pus and epithelial cells, various cocci and bacilli, a few diplococci, but no tubercle bacilli. Examination of the nervous system and of the genitourinary tract gave entirely negative findings. The von Pirquet tuberculin reaction was found negative. At times the patient complained bitterly of pains in the ankles and wrists and in the shafts of the long bones. The diagnosis was pulmonary fibrosis with chronic bronchitis, probably originating from an incomplete resolved pneumonia, and causing the development of hypertrophic pulmonary osteoarthropathy. As the patient failed to respond to the usual methods of treatment for chronic bronchitis, he was advised to go south for the winter. I was told that the bronchitis had now subsided and that the acute symptoms of cold were much relieved, though the dyspnea remained the same.

CASE V. M. B., laborer, aged twenty-four years, born in Russia; entered the second medical service of the City Hospital in March, 1913. The history had to be obtained through an interpreter, as the patient spoke only an unusual Russian dialect. His chief complaint on admission was sharp pain in the epigastrium and at times in the back.

Personal History: Had been a laborer, and had used alcohol and tobacco moderately. He had suffered from the usual diseases of childhood, and also smallpox. Had had a number of attacks of bronchitis, and at one time was quite seriously ill from such an attack; from this, however, he stated that he quickly and completely recovered. Venereal infection was denied. He had lost fifteen pounds in weight during the past year; no cough, no night sweats. The feet had been occasionally swollen and painful; the wrists had also at times been painful, though never acutely so. These bone symptoms had lasted for the past ten years. The patient stated that his father, one brother, and his son, three years of age, had all had large hands and feet similar to those which he himself had. He was unable to give an actual description of the pain in the epigastrium and back, of which he complained, but from what could be obtained through an interpreter it would seem that these pains were probably myalgic in character.

Physical Status: The patient is a well nourished and well developed man of about twenty-four years of age; he does not appear to be acutely or seriously ill.

Head: The hair is abundant and normal. The eyes are normal, the pupils equal, regular, and react to light and accommodation: examination of ears negative; teeth and mouth in good condition; tongue clean and normal; no globular enlargement of the nose or thickening over the malar processes, as is so frequently seen in cases of this disorder.

Thorax: Apex beat is seen and heard in fifth interspace, 3½ inches to left of midsternal line. The heart rate is sixty-eight per minute; rhythm regular, and no abnormal sounds present, except that after vigorous exercise a soft systolic murmur appears both at mitral and aortic areas; no dyspnea elicited upon exercise. The respiratory movements are somewhat restricted, and, though the thorax is well and symmetrically developed; an area of dullness extending downward from the level of the third dorsal spine posteriorly on the right side, finally merging below with a liver dullness. The respiratory sounds over this area are somewhat restricted in transmission, but there is no apparent change in fremitus; many small mucous rales found over entire thorax, particularly the bases, but frequent examinations of the chest fail to show constant signs except the flattened percussion sound mentioned. Râles are constantly present but differ very much in distribution, character, and frequency. The veins over the thorax and abdomen and those of the upper extremities in particular are somewhat congested; the feet and especially the finger and toe tips are very much cyanosed. The cyanosis is increased on exercise. The abdomen presents nothing abnormal except a few fibromata or lipomata embedded in the subcutaneous connective tissue of the wall, hepatic border lies at costal margin; spleen and kidneys not palpable on account of rigidity of the abdominal muscles.

The Extremities: Hands and feet very large; wrists and ankles thick and large, and peristeme apparently thickened over the distal end of each of the long bones; fingers and toes very much swollen, and tips of fingers thickened, and, though blue in color, and much curved. The subcutaneous tissue of the hands and feet is apparently hypertrophied, but the bones do not appear to be. The ankles are particularly enlarged and the skin over them and the feet is chronically cyanosed and they show a dusky blue tinge, and are slightly tender to pressure. Patient complains that when he is on his feet for a long time considerable pain appears in the ankles, and when he is standing it would appear that a slight degree of pes planus is present.

Examination of the Blood: Hemoglobin, eighty-three per cent.; red blood cells, 5,700,000; white blood cells, 10,000; differential leucocyte count, polynuclear cells, fifty-four per cent.; lymphocytes, forty-three per cent.; mononuclears and transitionalis, three per cent.

Examination of the urine is entirely negative. Radiographic examination of the hands and feet by Dr. Hirsch shows an enlargement of the soft tissue of these members but there is no increase in the bony structures of either hands or feet, except that exostoses of the terminal phalanges are present to some extent. The periosseous covering of the distal extremities of the long bones of the leg and of the forearm shows a marked zone of proliferation. Wassermann reaction negative. Patient had no rise of temperature while in the hospital and in a short time was entirely free from pain and willing to leave for home. He was given no treatment of any definite character, it being simply designed to keep him in the hospital for observation. Considerable cyanosis was constantly present in the extremities, and on exercise it also appeared over the tarsal and plantar region of each foot; with a slight tingling of the face. Because of the characteristic changes in the extremities the case was diagnosed as one of pulmonary osteoarthropathy, but, unlike the instances previously observed, no primary pulmonary or medullary lesion could be definitely demonstrated, but was suspected. The patient gained weight constantly while in the hospital, ate his food well, and appeared to be perfectly happy and contented.

TWO CASES OF Luetic Keratitis.

BY JOSEPH I. BRAUNSTEIN, M. D.,

New York.

Clinical Assistant, Diseases of the Eye, Beth Israel Hospital; Visiting Physician to the Jewish Home for the Aged and Infirm, Mount Vernon, N. Y.

These two cases seem to bear out previous experiences as to the ages at which luetic keratitis might have been looked for in the younger ones previous to our knowledge of the Wassermann reaction and the unreliable histories given by the parents, the conditions being unknown to them, or they would not commit themselves.

While we are able to present those cases through a Wassermann reaction to establish lues as the positive etiological factor, we find difficulties of a different kind present, for the parents will not permit you to make a specimen of blood, or a Wassermann test from a child as in the case of patient, B. E., aged four, and even with difficulty unless you are dealing with a very intelligent person, will the parents allow you to draw blood from their veins.

Another point of interest is the relation existing between the severity of the case and the age of the patient. If conclusions can be drawn, it appears to me that, while the virus is apparently the same, the local symptoms vary according to the age, and if we are to continue to read Wassermann reactions by the number of plusses, then the Wassermann reaction will bear out the clinical pictures of these two cases.

Case I, Wassermann reaction of mother. + + +

Case II, Wassermann reaction of patient. + + + + Father of second patient says a Wassermann test from him was negative after a course of treatment.

Case I. B. E., little girl, aged four years, apparently in good health; the mother had two children, and had aborted once. This history I was unable to obtain from her until I induced her to have a Wassermann test taken and then she admitted that she had aborted once, saying that she could not understand how she became infected, and asserting positively that her husband was never sick as far as she knew, and I could not induce her to bring her husband in to have a Wassermann reaction taken. Wassermann reaction of mother +++.

Case II. M. K., young man, aged seventeen years, apparently in good health, thought he had a cold in the eye when he came to see me; personal history for venereal diseases was negative; I could not get a history from his father or mother for sometime, as they never called at my office, with the boy, but he consented to have a Wassermann reaction taken, the result of which was + + + +. A few days later, suffering from pain, his father came to my office with him. I then learned from his father that he had had a chance twenty-seven years ago, and had undergone a course of treatment for the same; a Wassermann test had been taken from him a few years ago and found to be negative; it is evident here that the mother acquired syphilis before conception, and hence the child was syphilitic.

Clinical picture.—The clinical picture of each case varied and it may be correctly so if the severity of the case can be considered according to the number of plusses, and so as to prognosis of total disappearance of the local cutaneous infiltrations.

Case I (O. D.), subjective symptoms; photophobia, limited lacrimation; very little pain; interference with vision present. Objective symptoms: Cornea stema; infiltrations scattered; ciliary injections very little; pupil dilated.

Case II (O. V.). The subjective symptoms were marked photophobia; lacrimation; severe pain, and interference with vision. The objective symptoms were stema cornea; infiltrations of larger size; marked ciliary injection, and little dilatation of the pupil.

Treatment.—Case I, internally—calomel, one eighth grain was given five times a day. Locally—atropine one per cent. solution, one drop in the eye, four times a day, with calomel powder, dusted in the eye once a day; unguentum hydrargryi oxidi flavi (one per cent.) applied locally once a day. Hot applications of a teaspoonful of boric acid to a glass of water, four times a day, locally. In addition to all other treatment, unguentum dionin five per cent. was used to increase the blood supply and cause absorption of the remaining infiltrations, which had a tendency to remain as macule.

Case II. This patient I had to keep under observation and see at my office two and three times a day, as he was careless and, probably, unable to get some one to treat him properly, and he refused to stay in a hospital. Internally, I gave him pilula hydrargyri cum creta one grain every two hours. Locally, atropine solution four times a day; unguentum hydrargryi oxidi flavi (one per cent.), once a day locally; calomel powder, dusted in eye once a day; inunctions of mercury; and hot applications four or five times a day.

I advised the patient to enter the hospital that I might give him an injection of 666, which according to experience has a great effect upon external diseases of the eye by improving the photo-
phobia and lacrymation. The patient refused to stay in the hospital, after he was admitted, and I gave him intramuscular injections of salicylate of mercury once a week.

224 East Eleventh Street.

Prize Essays.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXXXVII.—How do you treat threatened abortion? (Closed August 15th.)
CXXXVIII.—How do you treat insomnia? (Closed September 15th.)
CXXXIX.—How do you treat chancreoids? (Answers due not later than October 15th.)

CXL.—How do you treat the symptoms of senility, without organic disease, but showing approaching dissolution? (Answers due not later than November 15th.)

Whoever answers three of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable, no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXVII has been awarded to Dr. W. C. Hess, of Cresco, Iowa, whose article appears below.

PRIZE QUESTION CXXXVII.

THE TREATMENT OF THREATENED ABORTION.

By W. C. Hess, M. D.

Cresco, Iowa.

Success in the treatment of threatened abortion depends, largely, upon our ability to locate the predominating cause and to direct the treatment toward removing it. The being so many different causes of the condition, necessitates widely different treatment in the cases as they appear in the general run of the doctor's practice.

When confronted with a pregnant woman, having colicky pains which come on at frequent intervals, a frequent desire to urinate, very little if any dilatation of the os (possibly admitting one finger), slight hemorrhage and headache, I give her from one half to three quarters grains of morphine hypodermically, which usually causes the pains to cease; then follow this in a few hours with from fifteen to twenty grains of sodium bromide in one drachm of fluidextract of viburnum prunifolium every three or four hours, for several days. Absolute quiet and rest in bed are insisted upon, until there has been an entire cessation of pain and hemorrhage for four days.

This far, I think, the treatment of threatened abortion, as conducted by the medical profession in general, is largely the same, but the prevention of the recurrence of the original symptoms is the important part of the treatment. Here is where most of the mistakes are made, "mistakes of omission." I might say, for four out of every five patients are dismissed at this time, often only to return again at a future period; at the end of seven or twenty-eight days in my experience is a favorite time for the symptoms to recur. Therefore before dismissing the patient give her a thorough examination, striving to find the cause of the trouble.

If there is local irritation treat the cause of the irritation. Correct the acidity or alkalinity of the urine as the case may be; prohibit coitus; correct constipation with mild laxatives, cascara preferred, in the smallest dose, given three times daily, that is necessary to move the bowels regularly.

Prophylactic measures during pregnancy might be mentioned, such as keeping the parts clean and healthy by the use of baths and gentle tepid (not hot) douches from a fountain syringe, with the bag elevated not more than two or three feet.

If the uterus is retroflexed, use the mildest means possible to correct the position, postural replacement, and if it fails to remain in proper position, I use a small wool tampon just large enough to hold it in this position for from twenty-four to thirty-six hours. This may be repeated every three or four days for from four to six treatments.

Up to the present time I have had no bad results from the local action of the tampon; but common sense and judgment are necessary in the use of the tampon in cases of threatened abortion.

As about fifty per cent. of the cases of abortion occur at, or near, the third month, it is wise to use special caution at this time and have the woman kept quiet and, at the least sign of anything out of the ordinary, have her go to bed and remain quiet.

We often have women with increased sensitiveness to nerve stimulation, especially at the usual menstrual time. In these I find the use of suggestion, or a good plain talk, does them good.

Mechanical or thermic irritation must receive attention. Horseback riding, dancing, railroad journeys, straining, like lifting or reaching, running the sewing machine, etc., should be prohibited; also hot douches and, if douches are used at all, use tepid water, with the syringe bag hung low. Hot sitz baths and the use of the hot water bag should be absolutely prohibited.

Toxic irritation should be kept in mind, and the use of ergot, hydrastis, stypticin, and all of this class of drugs, if used at all, should be administered with great care. Personally I think they are contraindicated in threatened abortion. Diabetes and lead poisoning should be thought of and dealt with along general lines if present, not forgetting that the woman is pregnant. Pure fresh air is essential in this condition both day and night, keeping in mind that a pregnant woman has an excess of blood to aerate.

Anemia, if present, should be treated with organic preparations of iron, and during the pregnant state I find them easily taken.

Hyperpyrexia from any cause should be guarded against, and the proper use of cold water in the form of sponge bathing, or the cool pack, is better than any of the antipyretics.
Strumous women, suggestive of the tuberculous state, are usually anemic and here I use the same treatment as in anemia, adding an extra element of nutrition, possibly some of the standard preparations of codliver oil, and advising plenty of outdoor life.

Syphilis, which I encounter very seldom in a country practice, demands the use of the iodides. Here let me state that, in women nearing the menopause, and in those with considerable sclerosis or hyperplasia of the uterus, and having threatened abortion, the use of five grain doses of potassium iodide three times a day seems to cause much improvement.

Bacterial and placental toxines may account for certain cases of threatened abortion. In chorea gravidarum, threatened abortion several days after recovery from measles (barring dead fetus), hyperemesis (where the effort at vomiting is very slight and with little if any straining), and when symptoms of eclampsia exist, treatment by elimination is indicated and, as a rule, should be followed by the use of proper tonics. I do not hesitate to give epsom salts and calomel in these cases, and often with marked benefit. A certain number will, nevertheless, go on to the stage of inevitable abortion and have to be treated as such. I have had several patients, about seventy-five per cent., go on to full term after a carefully given course of elimination.

Psychic and reflex nerve irritation, like fright, mental shock, nasal operations, extraction of teeth, etc., should be guarded against. Quiet environment and palliative remedies should be used in these cases.

The treatment of threatened abortion is not so much the proper remedy for the condition per se, as it is a careful study of the individual case, striving at all times to find the cause of the trouble and directing the treatment accordingly.

A large proportion of the cases of threatened abortion, spoken of by the profession as a whole, should be placed in the criminal abortion list; this would eliminate a large amount of the sepsis in the true threatened abortion statistics and lower the mortality to quite an extent.

In my experience after you have eliminated the criminal or instrumental abortions from the threatened-abortion list, by following general lines of treatment, and at all times making good use of your judgment and common sense, you will have little cause for worry when it comes to treating threatened abortion.

Dr. J. H. Pritchett, of Louisville, Ky., remarks:

In discussing the treatment of threatened abortion it is necessary to say a few words in regard to those patients in whom abortion has occurred once or more. These patients having aborted once, are likely to do so again; for that reason we should institute measures to guard against abortion as soon as the patient comes under our care. In this class of patients abortion is threatened and prophylactic measures will be of great aid in helping the patient throughout the period of pregnancy. Coitus should be absolutely forbidden, as I believe it is an important factor in producing an abortion.

Work and exercise to the point of fatigue should be prohibited, especially during those days when the menstrual periods would normally appear.

Long motor trips and even frequent short ones should be forbidden. The patient should be advised to lead a quiet life during the first few months of pregnancy.

When the symptoms present themselves, the patient should be confined to a quiet, dark room, placed in bed and advised to limit the body movements, the patient being on her back as much as possible. In the treatment, we should have in mind the following:

1. The anxiety and excitement of the patient. 2. The pain, produced by uterine contraction. 3. The hemorrhage. 4. The sequelae.

1. Anxiety of patients.—By posture and quiet in a darkened room we tend to obtain both physical and mental rest. The diet should be restricted to liquids, and as few people as possible should be allowed in the room. Oftentimes sedatives must be used. The bromides are useful, also virburnum prunifolium. I have obtained excellent results from the following prescription:

B. Fluidextracti viburni prunifolii, 1 4. Fluidextracti hyoscyami, 1 3.
Sodii bromidi, 1 5; Elixiris aromatici, 1 5ii.
M. ft. solutio.

Sig.: A dessertspoonful in a little warm water every three hours.

This can be repeated oftener if the case demands; however, few cases will need it oftener than three hours. After the patient becomes easier, the intervals between the doses should be from four to six hours.

2. The Pain.—By the administration of this prescription we hope to lessen the force and frequency of the uterine contractions. The pain usually is not severe. Should the patient be neuritic, or should the pain be severe, one quarter grain of codeine sulphate, either by mouth or hypodermically can be given; should this be inadequate, from one sixth to one quarter grain of morphine sulphate, hypodermically given, will be sufficient.

3.—Hemorrhage.—If the hemorrhage is no greater than that lost at the normal menstrual period we need not be alarmed. The rest, quiet, and sedatives, as before mentioned, will aid a great deal in controlling hemorrhage. Elevation of the foot of the bed helps a good deal. In my opinion cold compresses to the vulva and over the region of the uterus are contraindicated, as they tend to increase the uterine contractions. This line of treatment may have to be kept up for three or four days, and in the majority of cases the patient will respond nicely; however, should the hemorrhage increase and persist, then actual abortion must be thought of, and consultation be called and treatment should be as advised.

After the cessation of the symptoms the patient should return to normal living gradually, constant watch being maintained lest any symptoms return. Light but nutritious diet should be given. No drastic purgatives should be allowed.

4. Sequelae.—The patient will feel weak and have but little energy. She should rest a good deal of the time especially during the first few days.
after getting up. Often tonics will be indicated, the bitter tonics or some iron preparation being useful, our whole aim being to get the patient back to normal gradually and safely.

Dr. Paul F. Ela, of East Douglas, Mass., states:

Threats are remote or immediate in their significance. The remotest threats serve to put us on guard against possible dangers. Among conditions recognized as threatening in a pregnant woman, are physical defects and deformities, chronic diseases, like syphilis, tuberculosis, cardiac or renal lesions or the development of malignant neoplasms. More regional than general are deformities of the pelvis, and disturbed anatomical relations in the pelvic organs. Still more sinister are acute intercurrent fevers, and accidents causing violence to the organs of gestation and to the fetus.

The more remotely threatening of these conditions should be corrected if possible. When deformities exist there demand rectification in proportion as they are directly influential of the region of the pregnant organs and call for the exercise of gentleness and care in the same ratio. Where chronic disease exists it must receive appropriate treatment but discussion of particulars would demand more space than can be used here.

Acute fevers in proportion to their violence are dangerous to the fetus. The more severe are practically sure to terminate the pregnancy. In any case where a fever is found in a pregnant woman if recovery from the disease follows, the convalescence should be prolonged, and the patient kept in bed until it is certain that if abortion is to follow, it will result from the fact that the fetus is already destroyed by the fever, and not by quitting bed too soon. The same is true of accidental injuries. In proportion to the severity of the original injury should be the duration of the physician's aftercare when the immediate effects have subsided without destructive effects on the fetus.

When all that the physician's knowledge suggests has been done to forestall the effects he fears, and in spite of his efforts there appears one or both of the symptoms of beginning expulsion—pain and hemorrhage—the only treatment is absolute rest of mind and body, in the care of the best nurse available. In fact, rest is the first and last treatment so far as the matter of threatened abortion is concerned no matter what measures are adopted to guard against the effects of deformity or disease.

Pain calls for morphine subcutaneously in doses sufficient to stop the pain. So long as hemorrhage does not supervene—one should be sure the hemorrhage is not "concealed"—abortion is not inevitable. On the other hand if hemorrhage appears as the first symptom absolute rest, supplemented with derivate measures may forestall the onset of contractions of the uterus.

If these measures do not suffice opiates and sedatives should be used in sufficient amount to quiet the circulation.

Unless the presence of feces in the rectum seems to cause discomfort, the bowels should not be disturbed. If the rectum must be emptied, it should be by a small enema.

Visitors should be excluded, unless they are as quieting in their effect as a good nurse.

Examinations should be gentle and restricted to the fewest possible. After the first one make none unless some symptom appears, which demands knowledge that is obtainable in no other way.

The patient's clothing should be loose and arranged so that she may be cared for with a minimum of disturbance. The bed should be comfortable, a firm mattress is best, and the covering suitable to the season. The room should be the best available, well lighted and ventilated, and so situated as to exclude noise.

The diet should be suited to the demands of the patient's system. In patients well nourished in the beginning, it would be better to err in the direction of starvation than the reverse. Foods which produce flatulence or other disturbances of the bowels should be especially avoided.

(To be continued.)

Ovarian Therapy in Pulmonary Tuberculosis.

Jaquerod, in Revue médicale de la Suisse, remande for May, 1913, refers to the well known prejudicial influence of the menstrual periods on the pulmonary condition in women suffering from tuberculosis. The exacerbations, with fever and sometimes hemoptysis, noted at these periods, may occur either where there is dysmenorrhea or menorrhagia, where menstruation is temporarily suppressed, or where no menstrual disturbance whatever exists.

The author has found that the administration of dried ovarian substance to these patients is sometimes remarkably beneficial. He reports ten patients in which ovarian treatment, besides more or less promptly inducing regularity of menstruation where it had been irregular, caused complete disappearance of febrile reaction and hemoptysis at the periods, and even brought the tuberculous process in general, previously progressing unfavorably, to a standstill. In but few cases other than those of this series did ovarian treatment not yield some measure of benefit, and in none did it produce any harmful effects. The author points out that Wittgenstein showed in animals that ovarian medication caused a longer survival after infection with the tubercle bacillus, and in view of his own clinical observations, believes the drug deserving of recognition as a valuable symptomatic remedy in this disease.

The initial dose of dried ovarian substance prescribed by the author is 0.2 to 0.5 gramme (three to seven and one half grains) daily, continued for a month. Thereafter the patients take the remedy only during the eight or ten days preceding menstruation. In cases with hemoptysis, however, it is best to continue the drug, in smaller doses, throughout the menstrual period. As for the total duration of treatment, no definite law can be established. As a rule, where the untoward phenomena have not recurred for two or three months, the medication
can be discontinued, to be resumed later, if necessary. If the general antituberculous action of the remedy is to be utilized, the latter will, of course, have to be continued a long time—a year, or even longer.

Treatment of Acne Vulgaris.—Galand, in *Quinzaire thérapeutique* for May 25, 1913, states, concerning the local treatment of acne, that the patient should be required each morning to carefully wash the affected part with hot boiled water, in which boric acid and sodium bicarbonate have been dissolved:

R Acidii boricii,........ t...........ãã ãi (30 grammae);
Sodii bicarbonatis,..............iiii (1000 grammae).
Acque bullitae,..............iiiiii.
Solve.
After wiping with a dry, clean towel, absorbent cotton pledgets dipped in the following solution should be lightly applied:

R  Aquae Sodii,...................1v (150 grammae);
Rescorilis,...................ii (0.15 grammae).
Sulphuris loot, i...........ãã gr. bxxv. (3 grammae).
Misce.
In the evening, if the skin shows irritation, the parts should be moistened with boroglyceride and dusted with starch powder.
Brocq enumerates the following measures:

R Sodii bicarbonatis,..................gr. v (0.3 grammae);
Magnesii oxidi,..................gr. iii (0.2 grammae);
Rhamni purpureae, ...............i (0.02 grammae);
Betanaphtholis, ..................ii (0.15 grammae).
Fiat cachet no. 1. Da tales no. xx.
Sig.: One cachet before each meal.
In the evening the parts should be washed with a naphtholated soap, followed by spirit of camphor.
A little of the following paste should be left on the lesions over night:

R Rescorilis,..................ãã gr. iii (0.2 grammae);
Saponis mollis,......................iiii (0.02 grammae);
Betanaphtholis,......................ãã (0.15 grammae);
Cretae preparatae,..................i (0.08 grammae);
Sulphuris praeparatae,..................gr. iii (0.05 grammae).
Petrolatii puri,......................3v (20 grammae).
Misce et fiat unguentum.
The amount of petrolatum in this preparation is to be increased or diminished, according to the effects produced.
In the morning, after the ablations, the following mixture should be applied to the face:

R Sodii boratis, ..................iiiiss (10 grammae);
Aetheris, ..................iiss (16 grammae);
Camphor, ..................3i (4 grammae).
Acque rosae, ..................iiii (90 grammae);
Acque destillata, ..................3v (150 grammae).
Fiat mixtura.
Sig.: For local use.
Galand emphasizes the fact that preparations containing resorcinol or sulphur, both of which tend to produce desquamation, should be employed with some degree of caution. In the simpler forms of acne warm boric or borated lotions, or lotions containing sodium bicarbonate, are of great service.
Milk with two per cent. of aluminum sulphate added has proved curative in the author’s experience.
Emulsion of the pustules and comedones is sometimes advisable.

Treatment of Poisoning by Neosalvarsan.—H. W. Bayly, in the *Lancet* for May 24, 1913, reports the case of a young man with primary syphilis, and otherwise healthy, in whom energetic treatment with neosalvarsan and mercurial cream injections, the former given in pairs of injections at intervals of only forty-eight hours, caused a febrile reaction and obstinate vomiting. The vomitus having been tested for arsenic, which was found in it in considerable amounts, plenty of barley water was ordered for the patient, with the idea that what he absorbed would assist in washing out the kidneys and the remainder, being vomited, would remove the arsenic excreted by the stomach. After four days, however, as the vomiting persisted and the patient was becoming extremely weak, a change was made, at the suggestion of C. Ogle, to two-hourly feedings of a mixture of milk and albumin water, commencing with doses of one ounce, to be increased in frequency and quantity if the vomiting stopped. This treatment had the desired effect, and after twelve hours the vomiting had ceased.

Treatment of Gouty Manifestations.—Debout, in *Paris médical* for February 22, 1913, is credited with the following combination, to be given in gouty migraine:

R  Extracti colchici cormi, i...........ii (0.2 grammae);
Quininae sulphatis, ...............ii (0.15 grammae);
Pulveris digitalis, ..........iiiis (1.5 grammae).
M. fiat pilulae no. xxx.
Sig.: One pill every evening.
For the relief of acute attacks of gout, the following may be administered:

R  Quininae sulphatis, ..................ii (0.3 grammae);
Fluidextracti aconiti, ..............iiiis (1.3 grammae);
Extracti colchici cormi, .............iiiis (0.5 grammae);
Extracti belladonnae foliorum, ........iiiis (0.2 grammae).
M. fiat pilulae no. xx.
Sig.: From one to four pills a day.

Treatment of Headache in Children.—Gaujoux, in *Presse médicale* for May 7, 1913, is stated to have found that obstinate headache in eleven children was due solely to insufficiency of thyroid secretion. In eight cases there were other signs of hypothyroidism, such as palpebral edema, anorexia, constipation, somnolence, and pains in the muscles and joints, but the remaining three presented a normal appearance. After a systematic study of the symptoms, with resulting exclusion of all the more usual causes of headache in children, one should without delay resort to the therapeutic test consisting in the administration of a thyroid preparation. A daily dose of from one third to three quarters of a grain (0.02 to 0.05 grammae) may be given without risk.

Treatment of Itching in the Presence of Jaundice.—L. Aldor, in *Neuvreux remèdes* for January 24, 1913, is credited with the following lotion to be employed for the purpose mentioned:

R  Rescorilis, ..................ãã gr. xv (1 grammae);
Mentholis, ..................i (0.02 grammae);
Hydragryi chloridi corrosivi, ......iiiis (0.02 grammae);
Glycerini, ..................i iiiis (20 grammae);
Acque coloniensis, ..................iiii (100 grammae);
Alcoholis, ..................iiiis (400 grammae).
M. f. solutio.
Sig.: To be used as a wash.
THE NEWER METHODS FOR THE DIAGNOSIS OF PREGNANCY.

The classic signs of pregnancy not infrequently prove misleading and sometimes only furnish positive information late in the course of the process when, perhaps, the condition no longer requires a trained diagnostican for its determination. During the last few years, numerous methods calculated by their advocates to afford an early and certain diagnosis have been vouchsafed. The antitryptic test of Jachmann, Rosenthal, and others; the miostagmin reaction of Ascoli; the epiphanin test of Mosbacher are examples. Unfortunately, the complexity of these procedures, the inordinate cost of the apparatus required, and the skill demanded to carry them out have so far restricted their employment to too few observers to render possible a determination of their actual value in practice. Much the same drawback applies to the complement fixation test of Fieux and Mauriac, which requires, as antigen, an extract of a placenta derived from an early therapeutic abortion, a source which can only be available at best in large hospitals or maternities. Though requiring somewhat expensive apparatus, another method, that of Aberhalden, of the University of Halle (vide Hoppe-Seyler's Zeitschrift für physio-

logische Chemie, lxxvii, fasc. 4), is deemed less complicated. It is a polarimetric method applied to placental peptone which when used with adequate precautions and proper materials is said to give very satisfactory results, though, according to Bollafia (Pathologica, v. No. 11) it seems more reliable to affirm the existence of pregnancy than to denote its absence. A case reported by Veit (Zeitschrift für Geburtshilfe und Gynäkologie, lxii, No. 2, 1913) emphasizes, however, its value on the positive side of the question, and indicates precisely where any such diagnostic method, if reliable, assumes vast importance, particularly in the protection of the innocent. In Veit's case, the patient, a young unmarried woman, presented the major signs of pregnancy, much to the detriment of her reputation. Aberhalden's test having excluded pregnancy, Veit boldly opened the uterus and found therein a large myoma, which he removed. Although with Bollafia he does not deem the test absolutely reliable, he nevertheless regards it as a distinct acquisition, not only for the diagnosis of pregnancy, but also of tubal pregnancy, chorioepithelioma, and neoplasms of the ovaries and tubes. This belief would seem to be invalidated, however, by the fact that Engelhorn (Münchener medizinische Wochenschrift, March 18, 1913) found that normal serum was capable of dissolving carcinomatous tissue, but Franz and Jarisch (Wiener klinische Wochenschrift, September 26, 1912) showed that the trypsic digestive activity of the serum of twenty-six pregnant women was 0.8 or 0.9 as compared to 0.4 or 0.5 in nonpregnant individuals, and, moreover, that the index was also unusually high in cases of cancer. On the whole, when all possible sources of error will have been ascertained and corrected, it is probable that out of the many diagnostic methods recently proposed, one or more may prove of undoubted value.

ORAL SEPSIS AND ITS DANGERS.

Until comparatively recently the serious consequences likely to result from septic oral conditions were not at all adequately appreciated. Thus, for instance, pyorrhcea alveolaris was generally thought of as simply an offensive local disorder, and as the not frequent source of systemic infections, sometimes mild and sometimes of the gravest character. During the past few years, however, the subject has attracted considerable attention, and various writers have shown the probable, if not positive, causal relationship of oral sepsis to irregular febrile disturbances, aural disease, serious forms of anemia, arthritic affections, and other pathological conditions. It has been asserted, on apparently reason-
able grounds, that infected teeth may be the cause of various neuroses and psychoses, and not long since Joseph Collins published some experiences which had convinced him that serious organic disease of the nervous system may originate from Riggs’s disease.

The last paper written by the late Dr. Francis P. Kinnicutt, which he read at the meeting of the Practitioners’ Society of New York, was on the subject of oral sepsis. In this he especially emphasized the fact that local symptoms of pain and discomfort are often insignificant, while the local signs, on superficial examination, seem inadequate to explain the systemic disturbance. The obvious local signs may consist in no more than caries of one or several teeth, a contiguous gingivitis, and not infrequently an associated diffuse pyorrhea alveolaris of varying intensity. It has apparently been demonstrated, however, that the microorganisms of dental caries are particularly virulent, and it is only the natural resistant powers possessed by the tissues of the mouth which prevent their effects from being more commonly disastrous. His experience, he states, has been wholly in accord with that of Munter, who has published various communications upon the subject, showing that many slight, ill defined disturbances of health, as well as grave systemic disturbances, may be traced to oral sepsis. In addition to cases which he reports in detail, he refers to one of severe oral sepsis associated with grave anemia and combined sclerosis of the cord which had recently been under his observation at the Presbyterian Hospital.

Notwithstanding all that has been written in regard to the matter, it is to be feared that even now the dangers of oral sepsis are not as generally appreciated as they should be by the profession, to say nothing of the public at large. Dentists have been laying much stress upon the importance of “clean mouths,” but at the same time there is reason to believe that in a considerable proportion of instances the oral sepsis is directly attributable to their own crown and bridge work, now so much in vogue; presenting, as it does, a constant nidus for possible infection. After all, the great point to be striven after is prevention, and the most encouraging feature of the present situation is the recognition of the detrimental effect of oral sepsis upon the physical and mental development of the child, and the consequent increasing attention which is being paid to the care of children’s mouths. Thus, in New York the Bellevue and Allied Hospitals have for the past five years maintained dental departments, and there are similar departments in the various dispensaries of the city and the Health De-

partment clinics for school children in the different boroughs, while that in Richmond is dental exclusively.

**MERCURIC CHLORIDE TABLETS.**

The increase in the number of deaths due to the inadvertent use of mercuric chloride tablets has been taken cognizance of by the American Pharmaceutical Association in resolutions recommending that these tablets shall be given a distinctive color and shape and sold at retail only in glass containers. As a matter of fact there are other antiseptic agents which are fully as efficacious as this one, without being so dangerous, and there is no real need for the popular use of these tablets at all. But in this matter it is a condition and not a theory which confronts us. Whether it is right or wrong, the public does use bichloride tablets, either with or without the advice of a physician. It is well, therefore, that proper steps should be taken to minimize as much as possible the danger of their inadvertent administration.

Some months ago we pointed out the fact that a number of these accidents would probably have been prevented had the bichloride tablets been made up in some unusual form, such, for instance, as a triangle. The suggestions hitherto made for safeguarding bichloride of mercury tablets have been restricted to warning through two of the senses, the sight and the touch. The taste and the sense of smell may likewise be enlisted by the addition to these tablets of substances which are either repulsive in themselves or suggestive of danger. The addition of a small proportion of quinine would warn the innocent taker that the tablet is not an ordinary “headache” tablet, while the addition of phenol, of a cresol or of some very offensive substance such as pyridine would likewise give warning through the sense of smell. The objection to pyridine is that its presence might be offensive when the tablets are being used for legitimate purposes under the direction of a physician. Moreover, pyridine has no particular association in the public mind with poisonous qualities. Carbolic acid, or one of the phenol group, would be less disagreeable and would also have the advantage that the phenol odor is generally associated in the public mind with toxic qualities, so that the patient picking up a bichloride tablet would be at once warned by the phenol odor of its probable toxicity.

All four senses could readily be appealed to in safeguarding the public against the inadvertent use of these dangerous tablets without entailing any particular hardship upon the manufacturer. The following suggestion offered by the American
EDITORIAL ARTICLES.

Druggist seems to furnish a combination of safeguards which would do all that is possible to prevent people from taking these tablets inadvertently. Incorporate small quantities of quinine, of pyridine or cresol, and of soluble blue, make in the form of a triangle, stamp the word "poison" on each tablet, wrap each separately in green paper, and dispense only in glass containers with a rough exterior. The adoption of the blue color is a good idea since no medicine except methylene blue and few or no confections are colored blue. By wrapping each tablet separately in paper the attention of the consumer will undoubtedly be arrested. Red would be a better color for this, however, than green, as red is already associated in the public mind with poison. We would also suggest that the word "poison," or better still, a skull and crossbones be printed on the exterior of the individual wrapper in white letters. These precautions would add to the cost of the tablets, but, since they are used in small quantities only, this would be of no great consequence. It is, of course, impossible to prevent would be suicides from resorting to the use of these tablets. No precaution can prevent this, but such precautions as are outlined above would be effective in preventing poisoning from them by inadvertence.

PENNSYLVANIA'S INSANE ASYLUMS.

The State and county asylums of Pennsylvania were roundly criticized by several speakers at the recent meeting of the Pennsylvania State Medical Association which took place in Philadelphia last week. Dr. William K. Walker, a prominent Pittsburgh alienist, denounced the housing and care of the insane of the State as barbarous, inhuman, and worthy of the dark ages. Under the politically controlled system to which they were subjected, the inmates were deprived of proper food, clothing, and bed covering. They were herded together under conditions which rendered the proper treatment of their mental disease impossible, while the brutality of their keepers was condoned by physicians and unpunished by the courts. Both the speaker and another alienist, Dr. Edward F. Mayer, attributed the morbid results in many of the patients, and the resulting accumulation of insane subjects, to the neglect and archaic system in vogue in these institutions, a large proportion of patients being curable under modern methods when these were judiciously utilized. An urgent plea was made to remove all institutions beyond political control, i.e., beyond the cupidity of officials. Unfortunately, there is a material difference between denouncing and the carrying out of measures calculated to correct existing conditions. Medical men often protest but fail to act, and the morrow will efface the plea as the wind effaces initials on the sand dunes!

A SO CALLED SOCIOLOGICAL PLAY AND THE MEDICAL PROFESSION.

We believe that we are voicing the feelings of at least the bulk of the medical profession in protesting most emphatically against the production of a certain drama, which is asserted to have received the endorsement of medical men. The desire to produce real sociological plays before a selected audience, or even before the general public, is certainly praiseworthy, but if there is put on the stage, under the guise of such a plea, a performance which antagonizes the laws of Nature, such an action becomes criminal. Last autumn, a play was staged with the view to enlighten the public on certain sociological questions, but it fell short of its aim; we do not speak of the acting, for we are not critics of the histrionic art, but we lay claim to being judges of sociological projects. The company which first introduced that play has made public in the New York Times of September 20th an outline of a coming drama which seems to deal only with the question of the limitation of offspring and the legalization of illegitimate children. The example given in the play is very poorly selected, and to make this example the basis for the plea of limiting childbirths shows very plainly the wrong direction which these so called eugenists seem to take. There are exceptional cases where a woman should not bear children, but these are relatively rare. A representative of the German socialistic party, Doctor Moses, proposed only lately the limitation of the number of children, but he was absolutely opposed by the saner members of his party, and by the German public. The views of the Catholic Church on this subject are beautifully expressed by Andrew Klarmann in Crux of Pastoral Medicine, which appeared in 1905.

Furthermore, it is not a question whether such a drama will appeal to the depraved sense of a certain class of theatergoers. The unfortunate situation is, so far as the medical profession is concerned, that the promoters of this drama assert that the play is endorsed by some of the leading men of the medical profession in America. We hope that the physicians who appear as endorsing the play will lose no time in withdrawing their names as its sponsors.
THE NOMENCLATURE OF TUBERCULIN DOSES.

J. Alfred Codd remarks in the 

Lancet for August 30, 1913, that it is an elementary psychological fact that the human mind cannot grasp fractions so readily as it can multiples, and of all the fractions in use by the physician that of the tuberculin dose is one of the greatest difficulty, running as it does into many decimal places. As a remedy for this difficulty he suggests the resort to two new and small units. The first has been used by others and is the cubic millimetre. The second is an original suggestion of Codd's and is to designate the one thousandth part of a cubic millimetre as a psilon. The name may be translated as a shred, an atom, or a residue. Its initial letter (in Greek) has not already been appropriated to numerical nomenclature. Therefore we would have 1,000 psilons = 1 cubic millimetre, and 1,000 cubic millimetres = 1 cubic centimetre. Fractions are thus obviated, and the smallest tuberculin doses may be expressed as psilons or multiples of the psilon until the cubic millimetre is reached when this unit and its multiples are then appropriate. Codd also advocates the expression of tuberculin doses in terms of cubic centimetres or their fractions, as already indicated, rather than in terms of milligrams of the original substance, thus further simplifying the terminology greatly and rendering it more rational.

A CASE OF PELLAGRA TREATED WITH SALVARSAN.

D. W. Kelly, reporting in the New 

Orleans Medical and Surgical Journal for August, attributes to 
salvarsan the recovery of the patient, in this case a woman who had become ravingly insane, and was so emaciated that she weighed but seventy-five pounds. He gave her three grains of salvarsan intravenously June 11, 1912, and continued the administration, at intervals of ten or fifteen days, and in gradually increased doses, until August 1st, on which date he gave her the fifth and last dose, with the maximum amount—nine grains. By autumn she had completely recovered. Her mind is perfectly restored, and she now weighs 175 pounds.

Obituary.

WILLIAM JOHNSTON BEATTIE, M.D., 

of Littleton, N. H.

Doctor Beattie was killed on Friday, September 26th, in Bretton Woods, by an automobile, as he tried to cross the road. He was thrown several feet and his skull was fractured. He died instant- 

ly. Born in Rye Gate, Vermont, in 1865, he received his medical education at the Bellevue Hospital Medical College of New York, from which he graduated in 1889. After two years of internship in Bellevue Hospital, he went to 

Littleton, N. H., where he practised during the summer, returning in the winter seasons to New York. During the spring of 1912 he attended clinics in Vienna and Berlin, in which latter city he studied at Pirorkowski's laboratory and thus became acquainted with Pirorkowski's treatment of tuberculosis with turtle vaccine. Doctor Beattie was an esteemed contributor of our JOURNAL.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, October 6th, Will's Hospital Ophthalmic Society, Academy of Sur- gery, and the Philadelphia Clinical Association; Tuesday, October 7th, Aid Association of the County Medical Society, directors; Wednesday, October 8th, County Medical Society; Thursday, October 9th, Polyclinic Ophthalmic Society, and the Pathological Society; Friday, October 10th, Northern Medical Society.

Officers of the American Physicians' Study Travels.—At the Minneapolis meeting of this organization the following officers were elected: Presidents, Dr. James M. Anders, of Philadelphia, Dr. William J. Mayo, of Rochester, Minn.; Dr. Llewellys F. Barker, of Baltimore; and Dr. Raphael Matas, of New Orleans; secretary general, Dr. Albert Bernheim, 1225 Spruce Street, Philadelphia; department directors: Finance, Dr. L. Webster Fox; travel recordor, vacant; publicity, Dr. Alfred Stengel; postgraduate work, vacant; travel manager, Dr. E. E. Montgomery.

Missouri Valley Medical Society.—At the twenty-sixth annual meeting of this society, held in Omaha, Neb., on Thursday and Friday, September 18th and 19th, the following officers were elected to serve for the ensuing year: Dr. Flavel B. Wood, of the University of Missouri, president; Dr. Granville Ryan, of Des Moines, Iowa, first vice-president; Dr. Austin McMichael, of Rockport, Mo., second vice-president; Dr. O. C. Gebhart, of St. Joseph, Mo., reelected treasurer; Dr. Charles Wood Peasoll, of St. Joseph, Mo., reelected secretary. The next meeting of the society will be held in Lincoln, Neb.

The Reporting of Veneral Diseases in Pennsylvania.—The House of Delegates of the Medical Society of the State of Pennsylvania, at the annual meeting of that or- ganization held in Philadelphia last week, adopted a resolu- tion endorsing a proposition presented by Dr. Edward Martin, of Philadelphia, to make venereal diseases report- able to the health authorities of the State in the same man- ner that other communicable diseases are reported. The resolution was adopted without a dissenting vote and its action of the governing body was communicated to the members of the society at a later session.

New York Neurological Society.—The next regular meeting of this society will take place at the Academy of Medicine, on Tuesday, September 29th, at 7:30 P.M. The special feature of the evening will be presented by Doctor Karps, Doctor Cli- menko, and others, and there will be a discussion on the intraspinal (Swift and Ellis) method for the treatment of ataxia (paresis) by Dr. W. Hough, clinical pathol- o gist to the Government Hospital, San Francisco, Dr. W. C. R. Byrd, of Philadelphia, Dr. W. H. More, of New York, Dr. W. M. F. Patch, of New York, and Dr. R. W. Putnam, of Boston, will present the clinical cases. A final resolution was adopted without a dissenting voice, that the annual meeting of the association. The formal dissolution on his death were adopted by the society.

A Course in Sex Hygiene at New York University.—Announcement is made by the chancellor of New York University that on October 19th a course of lectures for teachers will be instituted by the School of Pedagogy of the institution. The course will consist of ten one hour lectures, given on alternate Saturdays at 11:15 a.m. The aim of the course will be to give teachers a knowledge of the facts and truths relating to the sex life of the human being. The question of method will be treated only incidentally, and will form the special topic of a similar course to be given next year. Dr. Edward L. Keyes, Dr. Rosalie Slaughter Morton, Mr. George W. Hunter, and Dr. Thomas M. Ballot will be the lecturers.
Examination of Candidates for Assistant Surgeon United States Public Health Service.—Boards of commissioned medical officers will be convened to meet at the Board of Public Health Service, Washington, D.C., and at the Marine Hospitals of Boston, Mass., Chicago, Ill., St. Louis, Mo., New Orleans, La., and San Francisco, Cal., on Monday, October 20, 1913, at 10 o'clock a.m., for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Public Health Service, when applications for examination at these stations are received at the bureau. Candidates must be between twenty-three and thirty-two years of age, graduates of any medical college, and must furnish testimonials from two responsible persons as to their professional and moral character.

Society of Sanitary and Moral Prophylaxis.—The first regular meeting of this society for the season of 1913-1914 will be held on Thursday evening, October 9th, at 8:30 o'clock, at the New York Academy of Medicine. Dr. Edward L. Keyes, Jr., president of the society, will present a report of progress, and a report of the lecture work done under the auspices of the society will be presented by the secretary, Dr. Henry P. de Forest. A brief financial statement will be submitted by the treasurer, Dr. Andrew J. Gilmour. The paper of the evening will be read by Dr. Richard C. Cabot, of Boston, his subject being Are Sanitary and Moral Prophylaxis Natural Allies? A discussion will follow among those who will participate, being Mr. Robert Fulton Cutting, president of the New York Association for Improving the Condition of the Poor, Professor Maurice A. Bigelow, of Teachers College, Columbia University, and Dr. Luther H. Gulick, secretary of the Great Fire Girls' Association. The meeting is open to the public.

The Medical Society of the State of Pennsylvania.—The sixty-third annual meeting of this society was held in the Academy of Natural Science, Philadelphia, on Tuesday, Wednesday, Thursday, and Friday, September 23rd, 24th, 25th, and 26th, under the presidency of Dr. Lewis H. Taylor. The first three days were devoted to the transaction of business and the reading and discussion of scientific papers, Friday being devoted to clinics and social pleasures. The papers presented were of an unusually high order of excellence, and many interesting and important points were brought out in the discussions. There was a large attendance and the meeting was in all respects a very successful one. Officers for the ensuing year were elected as follows: President, Dr. E. B. Heckel, of Pittsburgh; first vice-president, Dr. Henry D. Jump, of Philadelphia; second vice-president, Dr. J. B. Amberson, of Pittsburgh; third vice-president, Dr. J. H. Wilson, of Philadelphia; fourth vice-president, Dr. J. H. B. McMurray, of Washington; secretary, Dr. C. Lee Stevens, of Athens; assistant secretary, Dr. William H. Cameron, of Pittsburgh; treasurer, Dr. George W. Wagoner, of Johnstown. Next year's meeting will be held in Pittsburgh.

Personal.—Professor Morris Jastrow, of the University of Pennsylvania, sailed for England on Saturday, September 27th, in response to an invitation from the Royal Society of Medicine of England to deliver a lecture on the History of Early Medicine in America. Dr. M. B. Hartzell succeeds Dr. Jay F. Schambreg, resigned, as assistant diagnostician and consultant to the Bureau of Health of Philadelphia.

Dr. Walter Bensel retired on October 1st as sanitary superintendent of the Department of Health of the City of New York, after occupying that post for five years, and after a total of twenty-one years' service in the department. Doctor Bensel retires on a pension.

The Robert C.spring, of Philadelphia, has been appointed successor to Dr. Ralph H. Stanfield as medical supervisor of the public schools of Philadelphia. Dr. Leonard W. Elly, of Denver, has been appointed associate professor of orthopedic surgery at Stanford University and Yale University, and Ralph W. Majors, instructor in pathology at the same institution.

Sir James Grant, of Ottawa, was made an honorary life member of the Canadian Medical Association, at its recent annual meeting held in London, Ontario.

Dr. Charles A. Neas has been appointed professor of applied anatomy at the Jefferson Medical College, Philadelphia, succeeding the late Dr. George McCallan.
was excellent. The vomiting ceased, the stomach regained its normal size, and the patient recovered rapidly.

**DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT.**

August 7, 1912.

**Dietetic Treatment of Constipation and Diarrhea.—** H. Strauss presents an outline of two kinds of diet, one free from cellulose suited to inflammatory conditions and the other rich in cellulose for the asthenic or torpid form of constipation. A diet for constipation should have for its object the bringing about of mechanical irritation, to increase peristalsis, and at the same time possess the property of increasing the watery content of the feces. Foods which give rise to fermentation of carbohydrates, as puree of apples, prunes, fruit juices, stewed fruit, fruit jellies, buttermilk, milk sugar for sweetening lemonade and fruit juices, honey, lenuloze, and a certain quantity of fat, cream, or sauce, mayonnaise, etc. To increase the fluid content, agar is suitable. Agar diet in the form of jellies as wine, lemon, coffee, cream, chocolate, etc. The preparation of agar combined with cascar, called regulin, is a suitable cathartic. Rye bread, graham bread, Tyrol fruit bread, salads, coarse vegetables, marma-
lades, cucumbers, tomatoes, celery, beans, vegetables as cabbage, which cause flatulence, are to be omit-
ted. Cold water on an empty stomach is of advan-
tage; waters rich in carbonic acid, unfermented grape juice, and light beer are useful. The author believes that for constipation, due to neurasthenia, the withholding of meat for a time is a benefit. Nourishment possessing astringent qualities should be omitted. On the other hand, a diet with astringent properties is desirable for the treatment of chronic diarrhea. It must be nonirritant and yet sufficiently nourishing. No cellulose, nor coarse fibred food, nor elastic tissues, should be used for the irritated intestines of chronic diarrhea. Articles allowed are chocolate, claret, whortleberry wine, tender meats, as birds and chicken. Butter is valu-
able where there is no pancreatic disturbance or fat indigestion. Patients with diarrhea are usually sen-
tive to cold, therefore attention should be given to the temperature of the diet.

**Pineal Gland Extract in Country Practice for Obstetrics.—** K. Wolf asserts that in from three to five minutes after an injection of pineal gland ex-
tract, strong pains with sufficient intermissions en-
sue, and that these pains are more easily borne than those which occurred before the injection. The pineal gland extract is not capable of furnishing new muscle tissue, and for this reason there will al-
ways be patients for whom forceps will be indi-
cated. It corrects a functional disturbance of the organ and spurs the muscle tissue to the extent of its action. Injurious or unpleasant after effects are probably rare. The use of pineal extract is there-
fore to be recommended.

August 14, 1912.

**Hydrotherapeutic Treatment of Lung Tuberculosis.—** F. Köhler summarizes his treatment as follows: Contrary to cold water treatment as has been practiced, hot water applications, recommend-
ed in tuberculosis and also for patients with fever, have been neglected. Hot water bandages, hot sitz

baths and full baths of five minutes duration, are

indicated in pulmonary tuberculosis, where there are no pronounced hemorrhages. Especially in anemia and rheumatic tendencies they prove most grateful. They also make expectoration easy and often abort fever. They may be used as an alternating treat-
ment to the giving of antipyretics and dry, hot packs where weakness and tuberculosis have not ad-
vanced too far.

**Secalysatum.—** Brömel states as a result of his experience and that of A. Loewy that secalysatum has not only all the beneficial constituents of ergot contained in one fourth of the volume of ergot, but in addition it contains a certain proportion of catamine hydrochloratum. The combination is palatable and easily taken. Some of the poisonous constitu-
ents are removed from the secale. The author tes-
tifies to its ability to stop bleeding and prevent hem-
orrhages due to inadequate contractions of the uterus.

August 21, 1912.

**Epiphysitis Tibialis Dissecans Traumatica Adolescens.—** Ebbinghaus concludes as follows: A traumatic ailment of one or both knees may arise during adolescence in otherwise healthy children of both sexes. The affection is more fre-
quent than is generally supposed. A better and more intimate acquaintance with this ailment is urged. The possibility of its presence up to the sixteenth year should be borne in mind. Since its presence can only be positively diagnosed by the Röntgen ray, this should be applied in all doubtful cases. The ailment is anatomically and pathologically des-
ignated as epiphysitis. It is best treated surgically by removing the inflamed part of the epiphyseal pro-
longations and treating the loose separated parts of the same. This procedure is not serious when per-
formed under local anesthesia. Healing is accom-
ploished in about three or four weeks, when, as shown by the Röntgen ray, anatomically, normal conditions ensue. In spite of the usefulness of gym-
nastics and sports for the bodily and mental devel-
opment of youth, the author does not consider force jumping of distances, excessive mountain climbing, especially in very great altitudes, nor foot-
ball playing, etc., desirable between the ages of
twelve and sixteen years. All training in these sports should be omitted during the adolescent period.

**Experience with New Borneval.—** Engelen states from his clinical experience the effects of new borneval, that the new form of the remedy is more easily assimilated; its sedative effects are as marked as those of the older preparation, in hysteria, ner-
rasthenia, or nervous restlessness, as a result of overexertion, etc. The author found that it had a decided influence over cardiac nerves, especially the subjective symptoms of palpitation, fear, etc. One can easily confirm the decrease in nervous heart excitation by simply palpatting the pulse. The vol-
ume pulse curves recorded by means of a pneumatic apparatus show that new borneval acts most favorably on nervous circulatory disturbances.

August 28, 1912.

**A Contribution to the Rhachitis Question.—** M.

Kassowitz speaks of the nervous irritability of chil-
dren of the present day. Although the ailment of
spasmophilia is proclaimed as being independent of rhachitis, both are said to arise from imperfect lime assimilation which brings about either an oversupply or just the reverse—a deficiency of lime in the body fluids. These directly opposite anomalies are supposed to have the same effect: namely, an increased irritation of the muscle nerve apparatus. The author emphasizes that the most frequent developments of excessive nerve excitation—namely, excessive diaphoresis and sleeplessness in spasmophilia—are not to be controlled, while neither one nor the other can be designated as a spasmodic symptom. For this reason there is nowhere in the voluminous literature on spasmophilia any mention of the excessive diaphoresis or of sleeplessness in rhachities. Under treatment by phosphorus emulsion (not cod liver oil) the bones became hard and the nervous disturbances quickly disappeared.

Increased Glycronic Acid Excretion in Infantile Tetanus.—Paula Freund reports a case of spasmophilic diathesis in an infant, five months old. There were typical spasms of feet and hands, facial phenomena, a feeling of great fear, and a slight elevation of the temperature. Malt soup, in quantities, suited to its weight, was given as its diet. Milk diluted with water to one half was given for one day; the day after there was no excretion of glycronic acid in the urine. Since glycronic acid is probably an intermediate product in the metabolism of carbohydrate nourishment, it follows that in this patient having a pronounced spasmophilic diathesis the metabolism of a diet relatively rich in carbohydrates, as malt soup, increased the excretion of glycronic acid.

**ZEITSCHEF** **FÜR AUGENHEILKUNDE.**

_Familiar Progressive Degeneration of the Macula._—Stargardt reports another family of three children who presented the typical characteristics of this rare disease.

**Physostol.**—A. Dutot describes physostol as a one per cent. sterilized solution of physostigmine in olive oil, to be obtained in sealed tubes containing five grammes. The clinical indications for its use are those of meiotics, to meet which it is to be preferred to aqueous solutions of meiotics because of its chemical purity and sterility, the accuracy of its dose, its strong persistent action, and the fact that it is nonirritating. It is particularly well fitted to use just before and after operations for glaucoma. He has also found it of value as a prophylactic in ulceration of the cornea, of which he gives three examples, one in a case of ophthalmodynamorrhrea in an adult, one in ophthalmia neonatorum, and one from a cause not given. In all three the ulcers healed without perforation. He also found it of value in a peculiar case of secondary increase of tension in a syphilitic iridocyclitis. It is difficult to say how far these remarkable results depended on the drug, and how far they were coincidental.

**LYON MÉDICAL.**

_Simple Sclerectomy in Retinal Detachment._—Aurand reports a case of detachment of the retina in which a pericorneal nonperforating sclerectomy, as first recommended by Bettermieux in 1910, brought about a considerable enlargement of the visual field of the affected eye and numerous retinal cicatrices denoting a permanent return of the retina to its normal position. The improvement had persisted five months at the time of writing.

_Anomalous Situation of Adrenal Glands._—J. Rebuff and A. Goyet report having found, upon post mortem examination of a tuberculous patient, both adrenals situated within the capsules of the kidneys, with the tissues of which they appeared, even microscopically, to be completely fused. This finding is of interest in connection with the pathogenesis of hypernephromatous tumors.
PARIS MÉDICAL.
August 9, 1913.

Primary Pharyngeal Sporotrichosis.—H. Gougerot and P. Quelhien report a patient with extensive ulceration of the pharynx and general emaciation, in whom, after treatment for syphilis and tuberculosis had proved ineffectual, the presence of a mycotic disease was suspected and to whom potassium iodide was given internally and locally, with resulting marked improvement in two weeks and complete recovery in six. Subsequent examination of the secretions and performance of the agglutination and complement fixation tests for the Sporotrichum Beurmanni showed that this organism had been responsible for the disturbance. The diagnosis of sporotrichosis can even more easily be made by placing some pus on Sabouraud’s glucose peptone agar, allowing it to stand at room temperature, and later examining it with the naked eye. The case reported represents a new clinical entity, being one of primary pharyngeal sporotrichosis without simultaneous skin involvement. In such patients four grammes of potassium iodide should be given internally five days in the week and gargling with a solution containing iodine and potassium iodide ordered. This treatment should be continued until the pharyngeal mucus shows no more parasites and the agglutination and fixation tests fail, as the organism is saprophytic and recurrences can readily occur. Where the iodide treatment is badly borne the prognosis is grave, as laryngeal involvement, succeeded by lung gangrene or tuberculosis, are apt to follow.

PRESSE MÉDICALE.
August 23, 1913.

New Method of Applying Radium Externally.
—E. Vallet, seeking to render less costly and hence more widely available the radium treatment of skin affections, conceived the idea of incorporating it in a relatively minute amounts of a nonirritating, odorless, colorless, stable, supple, and elastic medium, “greenette,” which is then welded and melted into a film, to be cut according to the shape of the affected area of skin and allowed to remain in contact with it for a prolonged period. With this plan the prolonged action of a small amount of radium is made to take the place of the brief, more intense action of a larger quantity, and the expense correspondingly reduced. The surface of the film is slightly warmed before application, then pressed down gently on the lesion until it is cooled and adheres. Two strengths of radium are employed, the one for large areas being four times weaker than that for small. In the former case no skin reaction is expected until the film has been in contact fifty days, and depilation occurs only about the sixty-fifth day. Accurate gradation of the effect is rendered possible, owing to its slowness. The treatment is evidently suitable for nevi, angiomata, epitheliomata, lupus, and papillomata, and may also replace the x rays, hot air, etc., where these are not available, in keloids, tuberculides and tuberculous adenitis, sycoysis, eczema, pruritus, and neuralgia, acne rosacea, xanthoma, exophthalnic goitre, rhinophyma, etc.

August 27, 1913.

Symptomatic Significance of Erythema Nodosum.—Aubert avers that in the last few years the view that erythema nodosum is a rheumatic manifestation has been seriously shaken. Tuberculosis underlies a certain proportion of cases of this condition, which should be looked upon as a symptom rather than a separate affection, and included under the term “bacillosis” which Landouzy has introduced to designate the acute inflammatory manifestations due to Koch’s bacillus. Attention would thus be better called to the identity of erythema nodosum as a pretuberculose disturbance and to the necessity of applying the treatment appropriate under this condition. The ophthalmic, intracutaneous, or other tuberculin test should be employed in erythema nodosum to ascertain whether tuberculosis is the cause. If the result is positive, the usual hygienic and dietetic measures should be instituted, and preferably also the administration of Marmorek’s serum, which in one of the author’s cases, after four months of vesperal fever and with positive eye reaction, appeared distinctly to promote recovery. Three other cases are reported illustrating the relationship of erythema nodosum to tuberculosis and the necessity of not always relying on salicylic medication in its treatment.

SEMAINE MÉDICALE.
August 20, 1913.

Partial Muscular Atrophy in Myopathic Disorders.—F. Rose reports a case of Erb’s juvenile type of muscular atrophy in which the autopsy, after tuberculosis had caused the death of the patient, showed marked differences in the degree of myopathic involvement of the several portions of the same deltoid muscle, in spite of the fact that no anomaly in the distribution of the circumflex nerve could be found accounting for these differences. All nervous structures examined, including the cord, were found normal. These findings are cited by the author in support of the muscular theory of the origin of Erb’s and other forms of muscular atrophy, as against the nervous theory.

ROUSKSY VRATCH.
June 15, 1913.

The Vindaw Sanatorium for 1900-1913 in Connection with a Sketch of the Status of the Fight against Surgical Tuberculosis at the Seashore Hospitals and Sanatoria of Western Europe.—N. A. Veljimoff presents the results obtained in the treatment of surgical tuberculosis in children at the Vindaw Sanatorium, located on the shore of the Baltic sea. For the thirteen years of its existence the sanatorium received 514 children, of whom 425 were suffering from bone tuberculosis and the other from rickets and scrofula (tuberculous adenitis). The average length of residence of the patients was 417 days, some children remaining in the institution over four years, and one over five years; 53.7 per cent. recovered, and 28.5 per cent. improved, or a total of 82.2 per cent. of favorable results. These results compare favorably with those obtained at the seashore sanatoria of Western Europe, with the exception of tuberculous adenitis, the patients doing somewhat better at ocean resorts. Summarizing all
the available figures, the author concludes that generally more than half of the cases of surgical tuberculosis in children treated at the seashore recover, one fourth improve, and one fourth receive no benefit. The author is decided of the opinion that for the treatment of surgical tuberculosis the seashore sanatoria are more beneficial than the inland institutions.

June 22, 1913.

The Effect of Malignant Growths on the Reaction and Alkalinity of the Blood.—A. P. Konikoff found that the presence of carcinoma or sarcoma produces a marked reduction in the alkalinity of the blood. This reduction is generally in proportion to the degree of emaciation from which the patients suffer.

June 29, 1913.

Comparative Determination of the Effect of Drugs on High Blood Pressure in Arteriosclerosis.—K. Rutkevitch found by a comparative study on cases of permanent high blood pressure that the effect of the nitrates is evanescent, lasting only two or three hours. Sodium nitrite, in doses of 0.05 to 0.1 gr. am, almost invariably produced unpleasant subjective and objective symptoms. Hyposin and vasotonin had no effect at all, while the iodosides reduced the pressure but slightly. He explains the excellent results obtained by other observers on the ground that frequently the pressure is lowered during the first few days of hospital regimen, and this reduction was attributed to the use of the drug. In the author's experiments this possible error was eliminated by commencing the observations several days after the patients were admitted to the hospital.

Colloidal Nitrogen in the Urine of Patients with Cancer.—A. P. Konikoff found that Salkovsky's coefficient of colloidal nitrogen in the urine is of little diagnostic value in carcinoma. In twenty-three cases of cancer only nine showed a coefficient higher than normal. Moreover, as has been shown by other observers, a higher coefficient may occur in other diseases, such as pneumonia, tuberculosis, rheumatism, nephritis, hepatic cirrhosis, and, particularly, typhoid fever and diabetes.

BRITISH MEDICAL JOURNAL.

September 13, 1913.

On Urinary Antiseptics.—Anson Jordan's experiments lead him to conclude that: (1) The taking of acid sodium phosphate readily increases the acidity of the urine to more than double its normal acidity; the benzoates increase the acidity to a considerably less extent. Large doses of citrates easily render it alkaline. (2) Putrefaction of urine, and the growth in it of *Staphylococcus aureus* is greatly aided by an alkaline reaction and is delayed by acidity in proportion to the degree thereof. With *Bacillus coli* the reverse is the case, but to a small extent only, for it grows quite luxuriantly in either acid or alkaline urines. (3) Hexamethylene-tetramine is not itself antiseptic, but acts by the liberation of formaldehyde. This takes place in acid urine only, the drug being inert in alkaline urine. The degree of the antiseptic action of this drug, other things being equal, is proportionate to the acidity of the urine, and where this is normal or above normal hexamethylene-tetramine is by far the most efficient of all urinary antiseptics. In spite of its decidedly different behavior in the test tube, there is no evidence that hexamethylene-tetramine, this statement applies also to citrimate, hetralline, and cystopurin. (4) Oil of sandalwood is a poor general antiseptic, but seems to have a specific selective action upon the staphylococcus, which fact applies to cocci in general. It is of some use in alkaline urine. (5) Benzoic and salicylic acids act very similarly and both are fairly efficient urinary antiseptics, but are of little use in alkaline urine. (6) Boric acid is a very efficient antiseptic, and its action is not affected by the reaction of the urine. It is the most efficient antiseptic for cases with alkaline urine. (7) Uva ursi is a good antiseptic, but its action as such is certainly not due chiefly to the arbutin which it contains. In addition to these conclusions, Jordan feels justified in drawing some practical deductions. He says that the use of hexamethylene-tetramine, together with acid sodium phosphate which should always be given along with it, is of the utmost value as a prophylactic before any operation or procedure in which the urine may become infected, since if the urine is highly acid, clean, and contains sufficient of the drug continually it becomes a powerfully antiseptic fluid and will not support the life of bacteria. Hexamethylene-tetramine should be given only where the urine is or can be made acid, it is otherwise inert. It should never be given along with potassium citrate in *Bacillus coli* infections. To make the urine alkaline in this infection, use boric acid and infusion of uva ursi. In cases of ammoniacal fermentation of the urine in the bladder, some operative procedure or bladder irrigation constitutes the most important parts of the treatment. Uva ursi, boric acid, and possibly sandalwood oil are the best drugs to use in these conditions. It is always worth while to try sandalwood oil in a cystitis due to staphylococcus alone. It is advantageous, while giving hexamethylene-tetramine, to occasionally test the acidity of the urine to make sure that the acidity is maintained high. A high degree of acidity is of greater importance than a large dose of the drug. As a guide to the degree of acidity, Jordan states that the normal urine of a specific gravity of 1.020 is such that ten cubic centimetres of it will exactly neutralize one cubic centimetre of decinormal sodium hydroxide solution, using phenolphthalein as the indicator. All of Jordan's experiments were carried out by infecting his own urine, previously sterilized by filtration through a Pasteur-Chamberland filter. After determining the rate of growth of staphylococci and of *Bacillus coli*, as well as the rate of putrefaction in the absence of sterilization, Jordan determined the influence upon these rates of changes in reaction. Then he proceeded to determine the antiseptic powers of the several drugs considered by taking each for several days, thus closely paralleling conditions as they might be expected to occur in the treatment of patients. J. W. Thomson Walker contributes some further information on this subject, and, while agreeing in greater part with Jordan's findings, differs in some essential matters, and approaches the question from a more purely clinical point of view. He calls attention to the ex-
istence of some decided fallacies in laboratory studies upon the question which tend to reduce their value. In the first place, in practice the infections are very often of a mixed type; secondly, in disease bacterial toxines are constantly being formed and removed; the element of the bactericidal action of the living tissues is large; and lastly, the urine in disease often contains a large amount of protein which tends to diminish the bactericidal action of the drugs used. In addition to these there are to be considered the two unknown elements of the absorption of the drugs used and of their rate and degree of excretion into the urine. In the case of Bacillus coli infection, with either an alkaline or an acid urine, he finds that the primary administration of potassium citrate until the reaction of the urine is strongly alkaline promptly reduces the constitutional symptoms of the absorption of the toxines but does not destroy the organism. If, then, subsequent to the reduction of all of the symptoms by alkali, acid sodium phosphate be given along with hexamethylenetetramine until the urine is decidedly acid it may be possible to sterilize the urine completely and promptly. In a series of 230 cases receiving hexamethylenamine, thirty-four per cent., or seventy-nine cases, showed no formaldehyde in the urine; but in these seventy-nine, hexamethyleneamine was being excreted as such in sixty-four. The reaction of the urine was alkaline in fifty-two of the sixty-four, and twenty-eight of these showed formaldehyde when the urine was rendered acid. Alkalinity of the urine absolutely prevents the liberation of formaldehyde, and there is little evidence for the suggestion that an inflammatory state of the mucosa has anything to do with the decomposition of hexamethylenamine.

Continuous Antiseptic Inhalation in the Treatment of Pulmonary Tuberculosis.—C. Muthu's long experience with this method of treatment, used in combination with rest, graduated exercise, and feeding has convinced him of its great value. He has found that the most useful method is to use a series of four solutions, thus preventing the treatment from becoming irksome to the patient, and to employ increasing strengths of the antiseptics. Formaldehyde vapor is the best drug, and can usually be given; if a patient cannot stand it, however, the last two formulae are suitable. The solutions are: (a) Formaldehyde, 2.5 per cent.; chloroform, one drachm; menthol, ten grains; pinol, ten minims: alcohol, sufficient to make one ounce. (b) Formaldehyde, five per cent.; guaiacol, one drachm; chloroform, two drachms; menthol, fifteen grains; pinol, fifteen minims: alcohol, sufficient to make one ounce. (c) Guaiacol, two drachms; terebene, one drachm; menthol, fifteen grains; pinol, fifteen minims; alcohol, sufficient to make one ounce. (d) Guaiacol, two drachms; iodine, one drachm; terebene, one drachm; and the remaining three ingredients as in the preceding formula. About ten drops of the solution should be sprinkled on the inhaler from every half to one hour.

Further Investigations of the Action of Digitalis on the Blood Pressure in Man.—Frederick W. Price has made prolonged and careful observations in thirty-seven cases, twenty-six of which were of some form of cardiovascular disease, and eleven of which were free, clinically, from any heart or vascular disturbance. The conditions of life, including diet and rest, were maintained as nearly constant as possible in each case during the course of observation, and the blood pressure readings were always made with the same instrument and at the same time of day in each. In only one case was there a rise of pressure, in several there was a fall, and in the remaining there was no change. It seems to have been shown conclusively that the internal administration of therapeutic doses of digitalis does not cause a rise of blood pressure in man. The fear of giving the drug to patients with arteriosclerosis is unwarranted, and the use of vasodilators in conjunction with digitalis is irrational and unnecessary.

LANCET.
September 12, 1912.

Remarks on the Treatment of Brain Tumor.—Charles A. Ballance holds that brain tumor should be regarded in much the same light as any other tumor, particularly when it is malignant, except that destruction of considerable areas of brain tissue leads to more permanent and disastrous results than similar injury to neighboring tissues elsewhere in the body. Early diagnosis is the prime essential for the welfare of the patient. One important difference does exist between infiltrating tumors of the brain and infiltrating tumors in other locations due to the fact that we cannot remove large areas of the brain substance as we can remove a breast or a uterus, and we are therefore limited in our treatment in such cases to the operation of decompression. This operation should be done before the symptoms have become more than barely sufficient to enable a probable diagnosis to be made; certainly one should never wait for pressure symptoms in the eye to develop, for these symptoms are associated with lasting damage to vision. Ballance contends that the great value of radical decompression is not appreciated as it should be by the practitioner. It has given more relief from pain and distress than almost any operation in the entire realm of surgery. It should be undertaken in the very earliest stage of the disease, and the decompression should be adequate in extent. It is insufficient to do a bone flap operation; a large area of bone on one or both sides should be removed completely. It is equally essential to open the dura and relieve tension. A cerebral hernia is the result desired. 'This is usually the only operation which can be resorted to in cases of malignant disease of the brain.

Anesthesia in Acute Inflammations of the Mouth and Pharynx.—T. B. Layton warns against the use of a general anesthetic in cases of quinsy, peritonsillar abscess, retropharyngeal abscess, and diffuse cellulitis in the facial planes of the neck and floor of the mouth, and says that most of these can be cared for without any anesthetic or with local anesthesia. The danger of inspiration of septic material and of severe cyanosis is too great under a general anesthetic to warrant its use except in the rarest cases. Most abscesses
associated with the teeth may be operated upon under gas anesthesia. Layton expresses it as his belief that the diffuse cellulitis of the neck and floor of the mouth, and the large, deepseated abscesses of the neck in relation to the pharynx, larynx, and carotid vessels are due to the teeth, and are further stages of the abscesses internal to the lower jaw.

Avoidance of Sudden Death from the Induction of an Artificial Pneumothorax.—Claude Lillington does not believe that death, or the serious accidents, such as pleural reflex, laryngeal spasm, gas embolism, aspiration pneumonia, and uncontrollable accidental pneumothorax from puncture or rupture of the visceral pleura, are unavoidable. He believes that the following "don'ts" are essential, and that if heeded there will be little tendency to accident. (1) Don't inject gas without satisfactory oscillations of the manometer, or at a pressure greater than that of the atmosphere when making the first injection. (2) Don't spare the use of local anesthetics, for both the skin and the pleura. (3) Don't create a high intrapleural pressure. A pressure of forty centimetres of water may cause no discomfort at the time of injection, but it may be more than doubled by a subsequent fit of coughing, and a leak in the pneumothorax may thus be started. The visceral pleura may thus be ruptured with a resultant accidental pneumothorax. (4) Don't induce a pneumothorax during menstruation when reflex excitability may be high. (5) Don't puncture on the first occasion in many different places in a search for free pleura. It is better to continue the search for free pleura after a day or two. (6) Don't inject gas rapidly, or at a low temperature. (7) Don't use large needles, or needles with rough surfaces; and don't allow the rubber tubing to drag upon the needle during an injection. (8) Don't inject until the patient is in a comfortable and easy position. (9) Don't hesitate to withdraw the needle at the earliest sign of collapse. (10) Don't operate without brandy and a hypodermic syringe full of ether handy. The needle should be introduced, if possible, only at a point where the lung is healthy. The greatest single preventive of pleural reflex and sudden death is the proper and efficient anesthetization of the skin, and more especially, of the pleura. This has been proved on animals.

A Study of the Use of Ice and Other Means of Preserving Food in Homes.—J. R. Williams finds that the data gathered in his investigation of this subject warrant the following conclusions: 1. The temperatures of cellars or living rooms in dwelling houses are not sufficiently low during the warm months of the year to protect milk and other perishable foods from rapid bacterial decomposition. Therefore an efficient refrigerator in the home is a necessity. 2. Most of the refrigerators in common use are almost useless and grossly uneconomical. 3. There is a large field for the manufacturer who will make a properly insulated and efficient box which can be sold at a moderate price. 4. If more economical methods of ice manufacture and distribution were employed, the cost of ice to the consumer could be materially lowered. 5. If to this saving were added that which would result from proper ice box construction, refrigeration vastly superior to that now found in the average home could be had for at least one fourth the present cost.

Morbidity Reports: Their Purpose and Present Status.—From his study of this subject, including many statistics in Europe and America, J. W. Trask believes that, as the control of disease presupposes a knowledge of its occurrence, it is of importance that every local health officer should know of the prevalence of disease not only in his own jurisdiction, but in neighboring cities and counties as well. In this country the State health department needs to know of the prevalence of disease throughout all parts of its territory, and also in neighboring States. For the purpose of the more extensive and more efficient public health work which is much desired there is needed a carefully worked out plan whereby all health authorities can be advised currently of the existence of epidemics and the prevalence of disease throughout the country. In addition to the information this would give of the approach of extending epidemic disease, it would add immeasurably to our knowledge of epidemiology. Such a plan depends, first, on the conscientious reporting of cases by the physician, and, second, on prompt reporting by the local authorities to the State health department. The scheme is not complete, however, without the reporting by the State health authorities to some common agent that will serve as a clearing house for the State reports and publish the data at frequent intervals for the information of all. The work of such common agent is now being done, in so far as is possible, by the Public Health Service.

Two and One Half Years' Experience with Salvarsan and Neosalvarsan.—W. T. Corlett, in addition to giving the results met with in 220 cases...
of his own, quotes largely from the published experience of others, and classifies the accidents following the use of salvarsan, according to the time of their appearance, whether shortly after the injection, from two to four days after, or from several weeks or months after. In giving his conclusions he says he does not wish to convey the idea that the use of salvarsan is to be discouraged. On the contrary, he believes that when the drug is properly employed, and by experienced persons, it is a most valuable remedy against the Spirochaeta pallida. To insure against untoward results, however, one must exercise great care as to the selection of cases and, after ascertaining that no physical disqualification exists, one should further exercise care in not giving too large doses. From his experience, he would advise that treatment be begun with a small dose, and gradually worked up by succeeding injections, not to be given oftener than once a week. Great care should be taken as to the purity and sterility of the distilled water. The reaction of the patient should be carefully watched, and if found very severe, further injections should be given with exceeding care. In cases of cephalic chancre one should institute salvarsan therapy with the greatest caution. If these precautions are taken the result will be, with rare exceptions, most gratifying, and if the drug is used in conjunction with mercury the result will be much quicker than with either alone. Again, there are many obstinate cases which will react only to this combined line of treatment. As to the relative therapeutic value of the old and the new salvarsan, he has been unable to detect any difference. Finally, every physician having had accidents from salvarsan should consider it his duty to report them, for in this way only can we arrive at a fuller and better knowledge of this last great stride in overcoming syphilis.

MEDICAL RECORD.

September 20, 1913.

Anaphylaxis and Asthma.—J. Matthews says that in anaphylaxis has been found the explanation for not only certain phases of immunity and over-susceptibility to infections, but also for various diseases and symptoms, such as asthma, hay fever, serum disease, urticaria, etc. The so-called asthmatic tendency has long been known to be marked in certain persons and families, and heredity has undoubtedly an important bearing on the etiology of the disease. There is no proof of the assumption that this predisposition is inherent in the nervous system, while it has frequently been observed that many of the individuals subject to heredity have very evident etiological factors in nasal polypi, suppurating sinuses, etc., the removal of which has relieved the asthma. From this it would appear that the essential inheritance has been an anatomical or functional predisposition to affections of the upper respiratory tract, probably associated with a susceptibility to anaphylactic sensitization. During the past four years about 300 cases of asthma have been examined in the Mayo Clinic, and in over ninety per cent. the principal lesions which might be considered etiological were in the upper respiratory tract. Various methods of desensitizing animals have been reported, yet none of these gives a lasting immunity, and all are attended by high mortality. Until a safe and efficient method of desensitization is possible, the treatment of asthma must, therefore, be directed, as in the past, to the relief of symptoms by whatever measures are indicated in each individual case.

The Administration of Tuberculin by the General Practitioner.—M. Solis Cohen believes that tuberculin, given in the way he advises, is the remedy par excellence in nearly all forms of tuberculosis, and that it can be given fairly safely if the following rules are observed: The initial dose must be minute. No patient should be given over one milligram of a milligramme at the first, and patients with fever should not begin on more than one tenth milligram. (At the present time he would advise against the general practitioner giving tuberculin in septic cases, in which the patients have high afternoon fever and very rapid pulse after prolonged rest.) The next most important thing is to observe and question closely for signs of a reaction before the second dose is administered. The interval between doses should at first be from five to seven days, but, in careful hands, after the first few doses an interval of three days may be allowed. There is no use in increasing a dose which seems to do good, unless it appears to lose its effect. A dose which causes a slight reaction, from which the patient recovers in a day, may be repeated; but must never be increased. When a dose causes a moderate reaction it should be reduced one tenth, the administration being withheld until all reaction symptoms have disappeared. Should a marked reaction occur, the treatment should be suspended for at least a week after the disappearance of the signs of the reaction, and then given in the dose of from one hundredth to one thousandth of that previously given. The increase in dose should be gradual (not exceeding 33.5 per cent. of the dose immediately preceding). The oral, hypodermic, and intramuscular methods of administering tuberculin seem equally efficacious, and the author prefers the oral. The dose by the mouth is the same as the hypodermic dose, and the reaction is the same, except for the local manifestation at the site of the injection. Finally, a repetition of caution, as a severe reaction means always damage, and sometimes death.

The Vaccine Treatment of Typhoid Fever.—From his personal experience in the past six years, and the statistics of others, W. M. Watters summarizes certain things he has learned and certain measures which can probably be improved as follows: 1. The best results have been attained by preparing the vaccine from an old nonvirulent culture which has been subcultured for years in connection with the Widal tests. A new culture is made from this, and incubated for twelve hours. 2. In comparing his dose with that of others it seems probable that his may be increased to 100, 200, or possibly 500 million. 3. An early diagnosis is most important; this can often be first made by blood culture, days before the Widal reaction appears. 4. The vaccines when properly used by an immunizer will not harm in any stage of the disease, or in
a relapse; but the earlier they are used, the greater the prospect of benefit. 5. A safe rule to remember is that the more severe the case, the smaller should be the dose. 6. The interval between doses is variable. A dose or two after the temperature has reached normal will render relapses less frequent.

The Absence of the “Sausage Shaped Tumor” and the “Mass per Rectum” in Intussusception in Infants.—L. M. Kahn states that in a recent article he called attention to the fact that these two well known signs of intussusception were often either not present or were late signs, and that, in order to decrease the mortality, it was necessary to make the diagnosis, if need be, without their presence. Additional experience has proved the correctness of this position, and it may now be confidently asserted that with a straightforward history of intussusception one may proceed to its operative reduction with security. The time lost in waiting for a sausage shaped tumor or for the intussuscepted gut to appear in the rectum may be sufficient to cost the life of the little patient. It would seem necessary to revise the teaching regarding intussusception so that with a history of sudden onset of screaming, intractable vomiting, and evidence of continuous pain and of blood and mucus in the stool, with an absence of fecal matter in the stool, a diagnosis of intussusception, particularly in infants under one year, may be safely made. There need be no great prostration at first, and this is the ideal time for operation. The x rays are now available for diagnosis in the doubtful cases, and should not be neglected.

ARCHIVES OF DIAGNOSIS
July, 1913.

New Apparatus for Freezing Point Determinations.—E. H. Bartley describes a simplified form of apparatus intended to facilitate freezing point determinations of the blood, urine, etc. Between two test tubes, one slightly smaller than and enclosed in the other, is placed a layer of alcohol. The inner tube receives the fluid to be frozen and the thermometer. Outside of the two tubes is placed another considerably larger tube, filled about one third full with ether or carbon disulphide, and so connected with an aspirator pump that when water is passed through the latter air is drawn through the ether or carbon disulphide in a series of bubbles, causing it to evaporate, cool the alcohol in the inner space, and through it, the liquid under examination. There is no necessity of adding ice to start the freezing, as is usually done in other forms of apparatus. The whole process is automatic, a simple electrically driven stirrer being used, and the observer merely regulating the flow of water through the pump and reading the thermometer. The apparatus is inexpensive.

Prognosis of Eclampsia.—A. Shulman asserts that the pulse is the best prognostic index in puerperal eclampsia. If it remains full and hard, and below 120, there is no immediate danger, but if it is weak, frequent, and compressible the prognosis is bad. A high temperature is not a necessarily unfavorable sign unless it exceeds 104° F., and is still ascending. It is less the frequency of the convulsions than the early occurrence of profound coma which may lead one to expect a fatal issue.

LONG ISLAND MEDICAL JOURNAL.
September, 1913.

The Role of Negative Currents in the Growth of Neoplasms.—Martin J. Sgier cites the physiological fact that in nerve and in muscle, every active or injured part maintains a negative electrical relation toward every other part which at that time is at rest or uninjured; that is, is normal and not active. Sgier suggests that this negative variation in the contracting or injured muscle may be the result of chemical changes occurring within the muscle tissue. On this basis he goes a step farther and concludes that these currents are “due to the chemical dissociation of molecules and atoms into negative and positive ions and electrons, whenever the equilibrium of a resting part was disturbed, whether by injury or by action; anabolism causing a positive electrical phenomenon and catabolism, a negative condition of the parts.” A muscle which is normal and at rest is isoelectric, being in electric equilibrium. Any cause which will upset this equilibrium will cause a current—any influence which lowers the vitality or in the slightest degree alters the metabolism of any portion of the muscle will create a difference of potential with reference to the undisturbed portion, and the altered portion becomes electrically negative to the normal. “The problem, therefore, resolves itself into a question of metabolism; whether it be a current caused by the perturbed and consequently lowered vitality (potential) of an injured or dying part, as compared with a healthy part, or one caused by the active metabolism and higher potential of an active part, as compared with one that is at rest. The currents will continue to flow until the equilibrium is restored, in every case.” As the question is one of metabolism, it is logical to believe that electric currents occur in all organs and tissues. Although none has been detected it is a reasonable supposition that currents must exist because of the vital changes (metabolism) which occur, and the consequent differences in potential which must be caused by them. In the case of a granulating wound, for example, the author believes it possible that the vis medicatrix is simply the electric current generated by the difference in potential between the injured and the healthy tissues. When the gap is filled up the electrical currents cease because the equilibrium is restored. Says Sgier:

Applying the foregoing to cancer or other tumors, the deduction would lead to the following conclusion or theory. A traumatism (mechanical, chemical, or thermal) exerted on a part of an organism or a tissue, devitalizes the tissue affected, lowering its vitality (altering its metabolism), and consequently generating, because of the difference in potential, an electric current or vis conservatrix. This electrical stimulation causes an increased growth of cells, which by their very presence further lower the vitality (by the added pressure which they exert on the blood supply, etc.) and thereby increase the electrical discrepancy (and consequently, the strength of the current) and augment or hasten the metabolism of the growth. It is a well known fact that cancer flourishes only after forty years of age, when the vitality is beginning to wane, and when the recuperative powers are no longer far in excess of the injury, so that the part of lowered metabolism has a chance to start (and thus add its weight to the
metabolic discrepancy) at a time when any organ or tissue that has recently or even remotely been injured or devitalized in any way (whether directly by traumaism or irritation, or indirectly, by interference with its nutrition or blood supply) has a poorer chance of a *restitutio ad integrum* than in early life, because of the general senile changes in blood vessels and tissues. Is it not possible that these senile changes may be reduced to a chemical basis, whereby new chemical combinations (ions and electrons) are formed, producing a state of metabolic equilibrium which is more readily altered or destroyed, and hence creating a condition in which these electric currents are more easily generated, and counteracted or destroyed with great difficulty, if at all?

Pursuing the same course of explanation further, Sgier regards metastasis merely as a process of autoinoculation with the products of metabolism from the primary growth, which are taken up and transported by the lymphatics. At the point where they lodge the tissues undergo chemical alteration, with the production of lowered vitality, in turn becoming negative to their surrounding tissues and stimulating cell proliferation as at the original focus. Sgier offers the foregoing hypothesis purely as a hypothesis which may possibly offer a clue to others, or which may stimulate others to profitable research along similar lines.

---

**Proceedings of Societies.**

**AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.**

**Twenty-Sixth Annual Meeting, held at Providence, R. I., September 16, 17, and 18, 1913.**

The President, Dr. Miles F. Porter, of Fort Wayne, Indiana, in the Chair.

The Treatment of Puerperal Streptococccemia with Intravenous Injections of Magnesium Sulphate.—Dr. James A. Harrar, of New York city, stated that the use of magnesium sulphate intravenously for the treatment of puerperal infection was first proposed by Dr. R. R. Huggins in 1910. Impressed with the results obtained by Doctor Huggins and interested in any means of combating the ravages of puerperal infection, Dr. R. W. Loberstine, upon his return from the meeting at which Doctor Huggins read his paper, tested the method at the New York Lying-in Hospital with more or less success. He effected a cure in three cases of streptococcal toxemia of the fulminating type that was so frequently fatal, and in one case of streptococcal bacteremia. His fifth and last case, one of streptococcal toxemia, but with negative blood cultures, resulted fatally, and rather discouraged him in the efficacy of the treatment. In continuation of this work, Doctor Harrar said he had employed the salt intravenously in nine additional cases of the severer type of puerperal infection, the bacteria having been demonstrated in the blood of five. The total series of fourteen cases, with complete recovery in twelve, had prompted him to present fever charts as clinical evidence of the value of this adjunct to our present means of dealing with puerperal infection, especially of streptococcal origin. A two per cent. solution of chemically pure magnesium sulphate was prepared with freshly distilled water. This was filtered and sterilized in half litre flasks in an autoclave. This solution would not hemolyze human red blood cells, and he had found by experience that prepared in this way it would not cause any temperature reaction in the patient. Formerly, a one per cent. solution of magnesium sulphate in physiological salt solution was employed, and a chill or sharp temperature rise frequently followed the injection. The author drew the following conclusions: 1. In the quantities and dilutions described, magnesium sulphate was absolutely harmless when administered intravenously to women suffering with puerperal infection. 2. Magnesium sulphate was of more value early in the course of the infection than after secondary localization had occurred. In the chronic cases of secondary thrombophlebitis or pyemia it did not appear to be of benefit. Its action was chiefly upon the organisms circulating in the blood. 3. It shortened the course of the bacterial toxemias in which the bacteria could not be demonstrated in the blood by culture, and anticipated the establishment of a bacteriaemia, and finally it had reduced the mortality in puerperal bacteremia, especially in streptococccemia, the most fatal form of puerperal infection, from ninety-three to twenty per cent.

In the discussion that followed, Dr. Ross McPherson, of New York city, said he had had very little experience with the actual treatment that Doctor Harrar had described except in watching his results. Only one case had come under his observation which was not a true bacteremia, and this patient did very well. The results described by Doctor Harrar were nothing short of marvelous as one saw these patients improve under magnesium sulphate.

Dr. Asa B. Davis, of New York city, said he had watched with interest, surprise, and gratification the work which had been done by Doctor Harrar in the cases that had come in his service, and he could confirm what Doctor Harrar had said.

Dr. Herman E. Hayd, of Buffalo, thought the results obtained by Doctor Harrar with magnesium sulphate in puerperal infection ought to stimulate all members of this association to try this treatment and at some future meeting relate their experiences in regard to it.

Dr. Gordon K. Dickinson, of Jersey City, said we were all interested in other types of bacteremia, and if Doctor Harrar could give us some points in the matter of pneumococccemia and the coecemias of other germs, it might instigate experimentation in different lines than those mentioned.

Dr. Budd van Sweringen, of Fort Wayne, said that if it be true that the establishment of an abscess in the lung, as in this one case the doctor recited, was responsible for the cure brought about, it bore out the contention of a Frenchman who wrote upon the establishment of abscess in these conditions by the injection of turpentine into the tissues of the thigh or back or any available place. He imagined the good results reported by the author at that time were due to a biological process, perhaps the establishment of antibodies in this "fixation abscess," as he called it, and whatever the theory might be a number of cases of his own were
treated in that way as well as others he had knowledge of and were followed by improvement. He had had no experience with the injection of magnesium sulphate, but he would like to know whether any of the Fellows had employed this fixation abscess method in streptococcic infections, and what results they had had with it.

Dr. Roland E. Skee, of Cleveland, said that we reported our wonderful successes, but did not report our failures. These observations and investigations should be followed up until it was proved that magnesium sulphate did what was claimed for it in puerperal infections.

Dr. Joseph H. Branham, of Baltimore, said that if all members of the association would carry out this method of treatment in cases of puerperal infection, in one year they would have absolute demonstration beyond a doubt of what there was in this treatment.

Dr. H. Wellington Yates, of Detroit, said it seemed to him the essayist attached very little importance to the toxicity of magnesium sulphate. In the report of cases he found that in each instance in which the magnesium sulphate was injected, there followed a distinct chill with rise in temperature. Therefore, magnesium sulphate should be used with care.

Dr. Edward J. Ill, of Newark, suggested that anyone who attempted to carry on these experiments with magnesium sulphate should not attempt to improve on the method adopted by Doctor Harrar, but wait until his paper was published, study it carefully, and then carry out the method as he had described it.

Dr. E. Gustav Zinke, of Cincinnati, said that this was a new method and that apparently had been practised with success, and it was their duty to take it up and determine what there was in it.

Doctor Harrar, in closing the discussion, stated that, as to the use of magnesium sulphate in other pathological conditions or infections, he had no experience with it except in one case of pneumococcic infection which occurred in the course of puerperal infection. In this case it was of no value. He did not feel prepared to make any final statement relative to the exact value of magnesium sulphate in puerperal infections, because he had not seen enough cases. However, sulphate of magnesium was certainly of value and well worthy of trial.

Lactation Atrophy of the Uterus.—Dr. Douglas H. Stewart, of New York city, stated that with lactation atrophy the breasts either produced too much mammary extract, and the uterus wasted away as a fibroid sometimes would when powdered cow’s udder was administered, or the secretion drained off in the milk, some hormone which should stimulate the circulation, nutrition, and growth of the uterus after the normal or physiological atrophy of the fifth month of lactation, and the physiological process became pathological in time. In the first case of his series her made the circulation right. After that lactation ceased, and growth and menstruation started at once.

Dr. Ross McPherson, of New York city, who opened the discussion, said he had wondered after seeing the case reported by Doctor Stewart, whether the secretion which was present in the patient’s breast was not the secretion that was found in many cases of pelvic disturbance. As soon as the disturbance in the pelvis was relieved, the secretion disappeared. The condition was interesting and rather unusual. He had not before seen a case of lactation atrophy that presented such symptoms.

Dr. David Hadden, of Oakland, said in a case he operated in two years ago there was no lactation connected with the menstruation. The woman had a baby four years before the time she saw her, and had not menstruated. Her uterus was retroverted, and both ovaries were prolapsed. There was a deep laceration of the cervix and an ulcer. He corrected these conditions, and two months after operation she began to menstruate and had since menstruated every month, the flow being practically normal.

Dr. Hugo O. Pantzer, of Indianapolis, said that the paper called attention to a class of cases that were too little touched upon in medical literature. About twenty-five years ago he confined a blonde who had all her previous life been in frail health. After being married for one year she conceived and had a child at full term. It was a forceps delivery. There were no complications incident to childbirth. The child in contrast with the mother thrived wonderfully and was nursed for two years. The family was very anxious to have an offspring, and the woman came to him at about the third year. He found a small atrophic uterus and complete amenorrhoea of some years’ standing. It was fair to associate amenorrhoea and atrophy of the uterus with excessive lactation. General remedies and the use of an intrauterine stem for a period of three or four months brought back menstruation, and the patient conceived again.

A Contribution to the Serology of Pregnancy.—Dr. Henry Schwarz, of St. Louis, said that it had been proved by the observations of many investigators that in diseased conditions of the various organs of the body, likewise in malignant disease and also during pregnancy the blood was contaminated by cell albumin from the affected organs, the malignant cells, and the chorionic villi, and that the organism responded to the entrance of this blood foreign material by the mobilization of ferments which effected the intravascular digestion of these proteins. It had also been proved that such ferments were not present in the blood of normal individuals. The protoplasm differed in these various tissues. This difference could be demonstrated by biological methods. These same methods proved that there was less difference between protoplasm from the same organs in different species than there was between the protoplasm of two different organs in the same individual. For example, there was less difference between the liver protoplasm of a dog and the liver protoplasm of a sheep than there was between the liver protoplasm of this dog and his kidney protoplasm. The protective ferments were specific. The serum of nonpregnant cancer cases would cause cleavage of cancer albumin, but not of placental albumin, and the serum from a noncancerous pregnancy case would cause cleavage of placental albumin, but not of cancer albumin. In the department of obstetrics of the Washington Uni-
versity Medical School Abderhalden's biological tests were used for the differential diagnosis of pregnancy; also for the early diagnosis of malignant disease and the control of such cases after radical operation. The biological test had been applied in more than 100 cases, partly in experimenta-
tion, and in a dozen cases as an actual and much needed help in diagnosis. Petri's assertion that re-
injecting an individual with some of his own serum would cause the appearance of nonspecific ferments was tested by repeating the experiments. The result was absolutely negative. Petri's second alleg-
ration that adding the active serum to inactivated pregnant serum would not restore the cleavage
power had already been disproved by Steising. Steising's experiment had been repeated four times, but always with positive results. In the service of the New York Lying-in Hospital and in the obstetrical service of the University of Pennsylvania and of Washington University, all toxemic and eclamptic cases were at present examined as to the degree of cleavage power of the serum. Where such power was impaired or absent, the attempt was being made to correct the conditions by injecting normal pregnant serum. It was hoped that such cooperation would in due time furnish reliable in-
formation on this subject.

Abdominal Cesarean Section.—Dr. Asa B. Davis, of New York city, presented the statistics with results for mother and child in the whole se-
ries of cases in which he had done this operation; likewise the indications for the operation. He de-
scribed the technic of the operation by a small me-

Treatment of Placenta Praevia by Cesarean
Section. When, If Ever, Is It Justifiable?—Dr. Ross McPherson, of New York city, stated that since 1891, in the service of the New York Living-
in Hospital, there had occurred 470 cases of pla-
centa praevia, and the operation of Cesarean sec-

The Advantage of Cesarean Section Over
Other Procedures in Border Line Cases.—Dr.
John Wilson Poucher, of Poughkeepsie, N. Y.,
reported five cases of Cesarean section, and in all of
them he used the high abdominal incision, open-
ing the uterus in situ as often as it was exposed, carrying the uterine incision well over the fundus.
With this incision the operation could be done through an abdominal opening about one half the
size of the lower incision, and the abdominal and
uterine wounds were separated by the contraction
and involution of the uterus. Another advantage
was that the uterine incision was made through a
part of the organ away from the larger bloodvessels,
and hence there was less danger of hemorrhage, and
he believed also a portion of the uterus was less
likely to rupture in subsequent labors. For pro-
tecting the intestines and to absorb any fluids which
were likely to overflow, one or two gauze pads, six
inches wide, six or eight feet long, were useful.
It had been said that Cesarean section had caused a
considerable number of ruptured uteri. He could
safely say that timely Cesarean section would pre-
vent most, if not all, ruptures.

In the discussion, Dr. Charles N. Smith, of To-
ledo, said that he had done twenty-three abdominal
Cesarean sections. Two of these were done in the
presence of placenta praevia centralis, one of them
particularly for that sole indication and the other in
the presence of transverse presentation in a woman
who had lost three children previously in labor and
who solicited this Cesarean section. The first case
was in a woman, twenty years of age, who was seen
at St. Vincent's Hospital, having had a profuse
hemorrhage. She was a primipara, with a very
small vagina, long, conical, rather firm cervix, with
not much dilatation, and placenta praevia centralis.
He did immediately an abdominal Cesarean sec-

The operation was performed by a competent and experienced
operator and amid suitable surroundings.

The Society of Obstetricians and Gy-

This content is an excerpt from the proceedings of a medical conference where various doctors presented their findings and experiences in obstetrics and gynecology. The discussion was centered around the use of Cesarean sections for treating placenta praevia and other cases requiring abdominal delivery. The presentations highlighted the advantages of Cesarean sections, particularly in cases where the placenta was near the cervix or when the fetus was in a breech position. The speakers discussed the surgical techniques, indications, and potential complications of such procedures. The discourse also included a critical analysis of the statistics and outcomes, emphasizing the importance of careful selection of cases for cesarean delivery.
Cesarean section for placenta praevia and some other indications.

Dr. James A. Harbar, of New York city, said he had had the pleasure of seeing Doctor Davis do a great many Cesarean sections, and there was no operation that he did more smoothly than a Cesarean section. At the New York Lying-in Hospital they all followed his technic. The speaker had operated on twenty-three cases by Cesarean section following Doctor Davis's incision, with perfect satisfaction.

Dr. H. G. Partridge, of Providence, said he had never seen a Cesarean section done for placenta praevia. He had seen cases of placenta praevia that showed a long rigid cervix, but these were very few. Practically all the cases he had seen had a soft, boggy, easily dilatable cervix, and within his own personal experience there had been no case which would have been suitable for Cesarean section. Within a week they had a case in the Lying-in hospital in Providence which was ideal for vaginal Cesarean section. This operation was done, the mother being in good condition afterward, but the baby was born dead.

Dr. E. Gustav Zinke, of Cincinnati, said there was no doubt in his mind that the majority of cases of placenta praevia could be relieved successfully, both mother and child, by the Fry method or the De Lee method, by balloon dilatation, or even by metal dilatation, although he had very little use for the latter. When they were able to watch these cases and had them in surroundings that were aseptic in character, they should see what they could accomplish by way of artificial dilatation and deliver per vias naturales, but when they had a case of placenta praevia centralis, for instance, which was usually complicated by an oblique or transverse presentation, the tampon would do no good, and before one succeeded in dilating the uterus successfully, either by the tampon, balloon, by manual or metal dilatation, the woman was usually so exsanguinated that if she did not die during the process of delivery, she would soon die after delivery, and the child, as a rule, was lost under these circumstances because it meant version of the after coming head. Besides, in primiparous women with these oblique presentations, he would not attempt anything except a Cesarean section. There were cases of marginal and lateral placenta praevia in which the hemorrhage was sometimes exceedingly difficult to control, and these were the cases in which a pathological condition pertained, in which the placenta was so implanted within the uterine wall that it had taken up much of the uterine musculature. Under normal circumstances the uterine wall was the same in every part, even under the placental site. Ordinarily the placenta did not occupy the muscularis at all, but only the serotina. In those cases the hemorrhage was not very excessive and it could usually be controlled; but when the placental tissue and villi had buried themselves into the musculature, then there was trouble in controlling the hemorrhage, and a timely Cesarean section would save both mother and child, while with the other manipulations they would probably have a fatal result so far as the child was concerned, and in many instances the mother was not saved. No man had a right to make a Cesarean section who was not thoroughly familiar with the technic of the operation. Every case of placenta praevia was a surgical one from the start and belonged to the hospital as truly as a case of appendicitis or any other surgical case, and there was no reason why these patients should not be sent to the hospital, even though the hospital might be ten, twenty, or fifty miles away.

Rupture of the Symphysi Pubis in Labor.—Dr. Henry Enos Tuley, of Louisville, said that careful research showed that there was but one case in from 30,000 to 60,000 births, including spontaneous and traumatic varieties. While recent writers stated that there were about 150 recorded cases in literature, these figures could not be verified, and Kayser’s estimate of about 130 cases, plus those since recorded, would indicate that the more correct estimate was about 140. It might be safer to state that the estimate varied from 140 to 150. It had long been the teaching that the articulations of the pelvis became softened and relaxed during gestation on account of the secretion from the synovial membrane lining their surfaces. The extent to which this softening occurred was not stated by the authors who referred to this phenomenon. He did not think it was so great as to cause difficulty in standing or walking in very many cases, at least such a condition had never been brought to his attention. The percentage of cases of ruptures which were caused spontaneously varied much according to different authors. Complications might occur in the form of rupture of the anterior vaginal wall, rupture of the bladder, severe hemorrhage from rupture of the veins about the vestibule, or suppuration of the joint or soft parts. After reviewing the literature, he reported a case of rupture of the symphysis pubis in labor occurring under his observation.

Conditions Complicating Pregnancy, Labor, and the Puerperium.—Dr. Asa B. Davis, of New York city, reported a case of threatened abortion, third month, due to myomatosis in the posterior wall of the uterus. There were uterine pain and bleeding. Myomectomy was resorted to, with uneventful recovery. Pregnancy continued, with normal delivery at term. A second case was one of acute dilatation of the stomach, in which there were great physical exhaustion, and prolonged labor due to ventral fixation of the uterus. There was low forceps delivery; marked dilatation of the stomach. Recovery followed. The third case was one of intermittent and unilateral chyluria complicating pregnancy and the puerperium. The pregnancy at the eighth month was complicated with double pneumonia; recovery. Normal delivery occurred.

(To be concluded.)

Letters to the Editor.

311 Spruce Street, Scranton, Pa., September 25, 1913.

To the Editor:

Theodore W. Schaefer, M.D., of Kansas City, Mo., questions the physicochemical food metabolism of certain alkaloids mentioned in my article on Carbon, Oxygen,

In his letter to your Journal of September 5, 1913, p. 590, he says that I make "certain statements that are variances, and in conflict, with the teachings of modern physiology and pharmacology" and that I say "among other things, that strychnine, morphine, atropine, hyoscyamine, and cocaine, when introduced into the body, become food to the tissues." He also refers to "nitrates of nitrogen," claiming that I suggest that "they cannot administer heat." He also defines food as "a substance, which when introduced into the organism, supplies material, that renews some structure, or maintains some vital process."

And again, "It (food) is distinguished from a drug in the respect that it supplies some vital action, while it does not supply the material, which sustains such action."

This seems to me to be rather postulational, but the doctor may be able to explain it, at least, to his own satisfaction. As for my part, I feel that he is at variance with modern scientific, chemical, physiological, and pharmacological facts. Just how a "vital process" may be modified without giving due credit to the material which when administered becomes responsible for such modification, is beyond my deductive and inductive powers of reasoning, or how any vitality can be restored without receiving food.

He takes for his thesis practically the same ground as myself in defining the word food. I have defined food as meaning "in the scientific sense, any substance that, being taken as food material or plant life, passes through organic action, to build up normal structure, or, to supply the waste of tissue."

Our ground for argument then becomes the same and to our further reasoning, there may creep in on one side or the other, error, and my statements, and conclusions as just both be right and still be opposed. Yet it is possible, and even probable, that we have both used truths. The doctor seems to be wedded to theory and undoubtedly thinks much of the wisdom of a certain Dr. A. M. Wilson, whom he quotes as saying:

"It is a fallacious theory, based on ignorance of physiology, that vegetable medicinal agents are tissue builders, blood makers, or reconstitutive agents. There is not a drug of vegetable origin, that reconstitutes or vitalizes. All real drugs are either animal (e.g. putatin, epinephrin, thyroidin, etc.) or mineral. The salts of lime, soda, iron, magnesia, and phosphorus in an organized state of combination together with a few from the animal kingdom are the ones to depend upon for reconstituting and regenerating the body."

I cannot see that Dr. Wilson's assertion proves anything except the fallacy of his hypothetical utterances. It is ipse dixit and not officially scientific. The first part of his assertion, in relation to "Drugs of vegetable origin" was as the ancients before physiological chemistry was properly and scientifically understood in the disposition, cleavage, and metabolism of the carbohydrates.

If his assertion in relation to the salts, etc., in the latter half of his quotation, is sane enough.

If Doctor Wilson's assertions and Doctor Schaefer's theories were true then were the vegetarians doomed to utter extinction and the majority of those with lingering sickness as good as dead, when necessary to call a physician, because no vegetable agent was a halting tincture and cure. It certainly seems to confound all my knowledge of chemical and physiological research concerning dietary metabolism to at last run up against that assertion of Doctor in such a letter, viz. "There is either a drug of vegetable origin that reconstitutes or vitalizes. All real drugs that act in such a manner are either animal or mineral."

That a dying, hungry system should discriminate between the media through which it receives desired life giving food and food reducing food, and declare the vegetable, while those offered via "animal or mineral," "robs me of all that I possess" (knowledge) and "makes me poor indeed." Yet I try to remember that the doctor is ipse dixit.

Doctor Schaefer's vital process theory in some respects needs revision. Speaking of the alkaloids he says: "When taken internally, these alkaloids are again partly eliminated from the body as such or are partly oxidized and destroyed in the process of tissue metabolism." Now, is not the whole of this article? That the alkaloids (carbohydrates) are destroyed (consumed) in the process of tissue metabolism? Just a difference in our dictation that is all. They are destroyed by being consumed as food in the process of tissue metabolism and by oxidation. He further confirms my theory when he writes: "It states that it maintains a vital process."

Here again we in harmony, for to maintain his "vital process" theory he must admit a "vital process" means a process of life and he cannot sustain or resustain a vital process through the process of destruction of the alkaloids I have mentioned contain the "elements of nutrition" but flatly denies it. This I will not attribute to ignorance, but rather to willful determination, the better to sustain his argument.

Now Doctor Schaefer would imply in his letter that I advocate toxic drugs as a standard daily food or a prolonged dietary. Any one reading my article will give me credit for limitations. I am not advocating these drugs, I am simply stating chemical and physiological facts concerning them, which remain interpreted within the intelligence of an mind sufficiently versed in the science of modern chemistry and medicine.

We know that vitality depends on food. I define food and Doctor Schaefer defines food and the formulae are practically the same. When a sick person receives drugs and medicines, if the body is furnished with any nitrogen, then they receive the elements of nutrition which will sustain life and tide them over disease until they can again eat food in larger quantities.

The doctor surely knows it is the elements in the food that vitalize and not the disease. The system must have these elements to sustain life. Now why does the doctor administer drugs, but to sustain life? He may tell you he gives drugs to metabolize disease which is only another way of saying he feeds the patient to produce both.

Again Doctor Schaefer says: "From these corollaries it is apparent, that if things were different from what they are, it would be impossible for the toxicologist to detect those poisons, in case of poisoning, excepting the last instance only would be recognizable by the toxicologist. They would be utilized and assimilated by the animal economy as food in the first instance."

I repeat what I said in my article, p. 377 in the last paragraph, viz.: "If we would prolong the life of a patient, he must be fed. Food then becomes essentially important in preserving the continuance of animal life. There are many ways to administer food. Any substance containing both a carbohydrate (carbon, hydrogen, and oxygen) and nitrogen, becomes food when assimilated by the animal economy. But such substances should be administered in the most concentrated form in order to become assimilated with the least possible exertion on the part of the patient's system. So we conclude that the concentrated form of the alcohol becomes the most available concentrated form, where quick, nutritive effect is desired. For prolonged, tonic, muscular effect, strychnine stands preeminent, and may always be relied upon, but not by the weak heart. In alcohol we have a nonnitrogenous food, a heat giver, which is consumed through the respiration. In strychnine we have a nitrogenous food, which furnishes tissue building material, and hence a flesh builder."

The body in which we are building up the carbohydrates, but the carbohydrates alone are food. Any substance containing carbon, hydrogen, and oxygen plus nitrogen will become food when introduced into the body of an animal as a quantity of normal metabolism and assimilation, whether drugs, vegetables, animal, or mineral. It is these elements which are necessary for life and the only way to prolong life is through food. It is positively absurd to say that these elements become food only when introduced into the system through animal or mineral media, and it is still more absurd to declare that
"there is not a drug of vegetable origin that reconstructs or vitalizes." The body when hungry is no respecter of forms or media. It needs food and fluids and will utilize them in whatever form or media they are presented.

J. C. DENSTON, M. D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The translation of Birnbach’s manual puts into the hands of English speaking physicians a work which differs materially in its scope from any other similar publication. The terse descriptions not only point out the anatomical and physiological peculiarities, but always tend to emphasize the clinical relation. The book cannot help but prove valuable to the specialist, particularly in children’s diseases and to the surgeon. To the general practitioner it will serve as a reference book in which he will readily find a clear statement regarding an unusual organic or organic condition which suddenly confronts him. The citations of the related literature given at the end of each section are quite complete and give an added value to the work. The author, who is a gynecologist, deems the obstetrical side of the utmost importance and deals in greatest detail with this side of the subject. The illustrations are mainly original, adding notably to the text.

For over fifteen years Dr. Carl Wegele has been foremost in Germany in the treatment of diseases of the gastrointestinal tract. Without holding any official position, the doctor has demonstrated the value of his teachings, which he laid down a few years ago, in his well known book "Therapie der Magen- und Darm Erkrankungen." The American edition before us is not only a translation of the German book, but Doctor Gross and Doctor Held have endeavored to add to the value of the original book by providing new parts and by making valuable addition to others. Doctor Wegele’s book is acknowledged as a work of great value and we can well recommend the American edition to our readers.

Meetings of Local Medical Societies.

MONDAY, October 6th.—Clinical Society of the New York Throat, Nose, and Lung Hospital; German Medical Society of the City of New York; Utica Medical Library Association (annual); Niagara Falls Academy of Medicine; Brooklyn Hospital Club; Roswell Park Memorial Hospital, Buffalo; Hornell Medical and Surgical Association; Hartford County Medical Society; Practitioners’ Club, Newark, N. J.

TUESDAY, October 7th.—New York Academy of Medicine (Section in Dermatology); New York Neurological Society; Clinical Society of the West Side German Dispensary and School for Clinical Medicine; Buffalo Academy of Medicine (Section in Surgery); Ogdensburg Medical Association; Oswego Academy of Medicine; Medical Association of Troy and Vicinity; Long Island Medical Society; Amsterdam City Medical Society; Lockport Academy of Medicine; Society of Alumni of Lebanon Hospital, New York; Hudson County, N. J., Medical Association (Jersey City); Bridgeport, Conn., Medical Association.

WEDNESDAY, October 8th.—New York Pathological Society; New York Surgical Society; Medical Society of the Borough of the Bronx; Alumni Association of the City Hospital; Medical and Pharmaceutical Association; Richmond County Medical Society; Dunkirk and Fredonia Medical Society; Alumni Association of the Norwegian Hospital, Brooklyn.

THURSDAY, October 9th.—New York Academy of Medicine (Section in Pediatrics); Society of Sanitary and Moral Prophylaxis; Brooklyn Pathological Society; Blackwell Medical Society of Rochester; Jenkins Medical Association, Yonkers; Buffalo Ophthalmological Club; Jamestown Medical Society; Society of Physicians of the Village of Amherst; Albany City Medical Club; Gloversville and Johnstown Medical and Surgical Association; West Side Clinical Society; Physicians’ Club of Middletown.

FRIDAY, October 10th.—New York Academy of Medicine (Section in Otolaryngology); New York Society of Dermatology and Genito-urinary Surgery; Eastern Medical Society of the City of New York; Society of Clinical Serology; Society of Alumni of St. Luke’s Hospital; Society of Ex-Internes of the German Hospital in Brooklyn; Saratoga Springs Medical Society.

SATURDAY, October 11th.—Therapeutic Club, New York.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending September 24, 1913:

Grubbs, S. B., Surgeon. Authorized to proceed to Venezuela and Brasil, R. I., when necessary for the purpose of making quarantine inspections.

Lundeen, L. L., Surgeon, to investigate an outbreak of typhoid fever at Martinsburg, W. Va., in cooperation with local health authorities; on rejoining station, directed to proceed to Crewe, Va., and advise with local authorities regarding the prevention of typhoid fever; then proceed to Durham, N. C., to inquire into the prevalence of pellagra in that locality.

McKen, Frank H., Passed Assistant Surgeon. Granted one month’s leave of absence from September 16 to October 15, 1913.

Williams, C. L., Assistant Surgeon. Granted leave of absence from October 15 to November 15, 1913.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Department of the United States Army for the week ending September 27, 1913:

Armstrong, John M., First Lieutenant. Medical Reserve Corps. Ordered to active duty for service at Fort Snelling, Minn., September 24th to 27th.

Christie, Arthur C., and Duncan, William A., Captains, Medical Corps. Ordered to proceed to New York, N. Y., and Boston, Mass., on official business pertaining to
the x-ray apparatus already installed at military stations in the vicinity of those places and the inspection of new apparatus now in process of construction, and upon the completion of this duty the officers named will return to their proper station. Falisi, J. Vincent, First Lieutenant, Medical Reserve Corps. Will remain on duty at Fort Logan H. Roots, Arkansas, until September 30, and will proceed to his home and stand relieved from active duty in the Medical Corps. Kennedy, J. S., First Lieutenant, Medical Reserve Corps. Ordered to Key West Barracks about October 3d for temporary duty. Kilbourne, E. D., Captain, U. S. Medical Corps, Detached on leave of absence, September 10th. Michie, H. C., First Lieutenant, Medical Corps. Left Walter Reed Hospital on September 10th on twenty-four days' leave of absence. Quade, O. H., First Lieutenant, Medical Corps. Reported at Texas City, for temporary duty. Quale, W. W., First Lieutenant, Medical Corps. Granted leave of absence for fifteen days. Scott, George H., Captain, Medical Corps. Ordered to Watervliet Arsenal for the physical examination of officers at that arsenal and ordered to the Philadelphia, Pa., Ordnance Department. Turner, John W., First Lieutenant, Medical Corps, National Guard of Missouri, and Waring, C. H., First Lieutenant, Medical Corps, Mississippi National Guard. Ordered to New York, N. Y., to report at Army Medical School, Washington, D. C., on October 2d to pursue the course of instruction at that school. Watkins, V. E., First Lieutenant, Medical Corps. Granted leave of absence for one month, to take effect upon the arrival of First Lieut. Logan, Capt. Capt., Medical Corps. Ordered to Fort Howard about September 30th for detached service in the field.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending September 27, 1913:

Married:

Cepelka—Pacak.—In Crown Point, Ind., on Thursday, September 18th, Dr. Jan Jaroslav Cepelka, of Chicago, and Miss Frances Pacak.

Burns.—In Bangor, Me., on Friday, September 19th, Dr. James Francis Burns, of Phillipsburg, Me., and Miss Mary Maloney, of Edwardsville, Ill., on Thursday, September 18th.

Ricker—Enterline.—In Harrisburg, Pa., on Wednesday, September 17th, Dr. Charles M. Ricker and Miss Sarah Enterline.

Hosmer.—In Youngstown, N. Y., on Wednesday, September 17th, Passed Assistant Surgeon Gardner E. Robertson, U. S. Navy, and Miss Frances Robertson, of Sylvania, Ohio.

Sutherland—Ramage.—In Hayward, Cal., on Tuesday, September 16th, Dr. Robert T. Sutherland, of Oakland, and Miss Ellen Ramage.

Stower.—In Plattsburg, N. Y., on Wednesday, September 17th, Mr. John C. Woodruff, of Plattsburg, and Miss Helen White, of Plattsburg.

Wright—Throckmorton.—In Burlington, N. J., on Thursday, September 18th, Mr. H. W. Wright and Miss Ellen Barbara Throckmorton.

Died:

Almy.—In Norwich, Conn., on Saturday, September 27th, Dr. Leonard B. Almy, aged sixty-two years.

Bailey.—In Fort Smith, Ark., on Monday, September 19th, Dr. William Bailey, of Fort Smith, and aged seventy years.

Beattie.—In Breton Woods, N. H., on Friday, September 26th, Dr. William Johnston Beattie, of Littleton, aged forty-eight years.

Becker.—In Mastersonville, Pa., on Saturday, September 19th, Dr. Phares Nauman Becker, aged fifty years.

Birdsall.—In Brooklyn, N. Y., on Wednesday, September 24th, Dr. Alfred Thornton Birdsall, aged forty-three years.

Cage.—In Carmel, Tenn., on Sunday, September 14th, Dr. James Edward Cage, of Tullahoma, aged seventy-six years.

Davis.—In East Orange, N. J., on Tuesday, September 16th, Dr. William H. Davis, of East Orange, aged fifty years.

Fahey.—In Wilmington, Del., on Saturday, September 20th, Dr. John C. Fahey, aged fifty years.

Henderson.—In Franklin, Tenn., on Wednesday, September 17th, Dr. Samuel Henderson Jones.

Jones.—In New York, on Thursday, September 25th, Dr. Roland J. Jones, aged fifty-seven years.

Leonard.—In Atlantic City, N. J., on Monday, September 22nd, Dr. Charles Lester Leonard, of Philadelphia, aged fifty-two years. McDonell.—In Chicago, on Thursday, September 18th, Dr. John A. McDonell, aged sixty-six years.

Neely.—In Bainbridge, Ga., on Friday, September 19th, Dr. John C. Neely, aged forty-three years.

Frees.—In New York, on Saturday, September 27th, Dr. Henry Thorne Peirce Sanden.

Sissors.—In Boston, on Thursday, September 25th, Dr. Orren B. Sanders.

Sigismund.—In New York, on Wednesday, September 24th, Dr. James Mordau Sigismund, of New York, aged seventy-five years.

Thomson.—In Philadelphia, on Sunday, September 21st, Dr. Frazier Thomson, aged forty-five years.

Whitacre.—In Detroit, Mich., on Sunday, September 14th, Dr. D. Frank Whitacre, of Romulus, Mich.

Wilm.—In Pulaski, Tenn., on Thursday, September 18th, Dr. Willy Wilm, of Pulaski, Tenn.

Willich.—In Brooklyn, N. Y., on Tuesday, September 23rd, Dr. Carl Willich, aged sixty-two years.

Wynn.—In Olympia, Wash., on Friday, September 12th, Dr. Hugh Summer Wynn.
DIFFERENTIAL DIAGNOSIS OF THE APPENDIX BY AID OF THE ROENTGEN RAY.

By A. J. Quimby, M. D., New York.

Clinical Professor of Radiography, New York Polytechnic Medical School and Hospital; Radiographer to the New York Foundling Hospital; Consulting Radiographer to the New York Nose, Throat, and Lung Hospital, etc.

The x ray study of the appendix has never had until now a scientific basis sufficiently strong and broad to warrant the assertion that such routine procedure is a necessary aid in separating appendicitis from the various pathological phenomena which occur in the right lower abdomen. Only occasional references have been made by several writers to the shadows formed by the appendix in radiographs.

The early experimenters in radiography of the appendix frequently met with failure because improper technic was employed. But after prolonged study of many cases and numerous examinations both fluoroscopically and radiographically, I have been able to indicate by examination of the cecum and the adjacent structures whatever condition may exist with accuracy.

In the examination of 141 cases between May 1, 1913, and September 15, 1913, data were obtained which enabled me to classify the appendix radiographically. Of this number, fifty patients had had laparotomies previous to the examination in which the appendix had been removed. Of the remainder, ninety per cent, gave sufficient data to determine the position and condition of the appendix. The remaining ten per cent., were those in whom the position of the cecum prohibited its thorough inspection.

The following classification covers the essential points in the findings of the average case, so that conclusions may be drawn that will permit a diagnosis to be made:

1. Functionating or nonfunctionating. 2. Fixed or movable. 3. Ascending, descending, or transverse. 4. Straight, kinked, curved, looped, or clubbed.

A functionating appendix is capable of receiving and discharging feces. In the human being it must be regarded as a part of the intestines and is therefore subject to the same laws. Accepting the fact of its power to receive and discharge material and using this as a basis for an analysis of its condition, we can then turn to the known laws with regard to the motility of the colon. The colon has been found to respond to a natural mechanical stimulus which starts a peristaltic wave at intervals of about four hours each. In examining the patient for stasis I have observed when the patient ingests a quantity of food or liquid the results are a decided forward movement of the bowel contents.

Accepting these facts of the normal four hour period, modified by ingesting food, etc., we may expect the appendix to discharge its contents under similar condition. Colonic peristalsis is inhibited at any point where a pathological abnormality occurs. As a rule, if there is any adhesion or constriction of the colon the peristaltic wave starts beyond this point at approximately normal periods. The repeated attempts of the bowel to carry its contents past an obstruction usually results in dilatation and eventual loss of compensation, with disturbance of peristaltic function and if, as physiologists believe, the normal wave of peristalsis originates in the appendix then we may expect a disturbance of function to occur in it whenever obstructive phenomena of material degree are manifested.

A nonfunctionating appendix may be incapable of receiving material because of the obliteration of its canal. It may receive feces and only discharge part, retaining the residue for indefinite periods. The writer has observed retained bismuth\(^1\) a number of weeks following an examination. In one case referred by Dr. S. L. Cash, and recently examined, the bismuth was found in the appendix when the latter was removed at operation.

The nonfunctionating appendix is always pathological, either having changes within its walls or dense adhesions surrounding it. Chronic inflammatory processes always end in replacing the normal structures with fibrous connective tissue. In the appendix such a process involving the muscular coat ends in loss of peristaltic motility; moreover, should connective tissue form in the other layers of its structure, or adhesions extending from adjacent parts bind it down, we have a degeneration of the muscle fibre caused by direct mechanical interference, disturbance of nutrition and reflex control, thereby causing diminished peristalsis. When this

---

\(^1\)The opaque salts used in this work are bismuth subcarbonate and barium sulphate. If administered in sufficient doses bismuth subcarbonate may be poisonous. This is due to chemical decomposition resulting in nitrate poisoning. If not properly washed barium sulphate may contain barium chloride, a soluble poisonous salt. Conservatively we may estimate that in x ray examinations 60,000 patients have received bismuth and barium salts with no ill effects, except where bismuth subcarbonate or impure barium sulphate was employed.
occurs feces with or without the normal food constituents may enter the appendix and be retained indefinitely.

The fixed appendix is usually adherent to the abdominal wall. Otherwise it is attached to the adjacent viscera that are held by adhesions which prevent displacement by manipulation. A type of fixed appendix is illustrated in the accompanying radiograph. Palpation or pressure while examining under the fluoroscope enables one to readily determine the degree of fixation. A portion of the appendix may be fixed, especially the tip or end, as quite a number of the cases examined have an adherent tip and free shaft; this results in a movable appendix in which mobility may be deceptive when the tip of the appendix does not contain the opaque salts.

A movable appendix may be so definitely changed in position as to delay its return to the original position or may be fixed at one segment, for instance the tip, and the remainder be readily displaced by shifting the cecum or, if of unusual length, the shaft will be readily carried to another position; if adherent to a movable structure its position can be changed by manipulation, in which instance a differentiation can be made if the attached viscera contain an opaque material. The general direction of a movable appendix can be so changed as to reverse it from the ascending to the descending type. As a rule the ascending type is adherent; the tip may extend to the transverse colon or liver. They usually point upward and inward to the right of the umbilicus and as a rule lie between the median line and the ascending colon. Several have been ob-
Radiograph 4—Mrs. McI. Referred by Dr. W. B. Graves. Ap. Appendix; C. cecum; A.C. ascending colon; I. ileum. This is a chronic appendix, nonfunctionating, of the kinked type, and adherent to the cecum.

Radiograph 5—Mr. W. Referred by Dr. W. S. Balchridge. Ap. Appendix; C. cecum; I. ileum; A.C. ascending colon; Sg. sigmoid; T.C. transverse colon; U. umbilicus; S. stomach; D.C. descending colon; R. rectum; Cn. constriction. In this case the appendix is adherent to the terminal ileum, is curved, transverse, and functionating. The favorable position permits it to readily drain in spite of the fact that it is adherent. Attention is called to the constriction on the ascending colon due to a mesenteric band which is, no doubt, the point of resistance in what appears to be a normal colon.

Radiograph 6—Mrs. G. Referred by Dr. H. D. Meeker. Ap. Appendix; T.C. transverse colon. This is a curved nonfunctionating appendix the tip of which is adherent to the inner side of the cecum, while the shaft was firmly fixed to the ileum. This appendix under manipulation through the abdominal wall could only be displaced a very short distance, while its curved even contour could not be changed whatsoever. Careful inspection of the radiograph will show that the tip of the appendix turns downward where attached to the cecum, literally producing a kink. The sausage like sections of hismuth can be readily perceived.

Radiograph 7—Mr. T. Referred by Dr. Earnest Bishop. Ap. Appendix; K. kink in the appendix; C. cecum; A.C. ascending colon; T.C. transverse colon. The tip of this appendix is attached to the sigmoid in such a position that, when the patient is horizontal, the cecum drifts upward and produces a kink at the juncture of the shaft with the adherent tip. This appendix was large, very easily palpated, and was nonfunctionating, retaining its hismuth several days.
QUIMBY: APPENDIX AND THE ROENTGEN RAYS.

connection with the inspection of the cecum, the ascending colon, and transverse colon, the greater the proportion of abnormal appendices. This is almost an invariable rule. Adhesions, mesenteric bands, and angulations involving the colon, resulting in stasis in the cecum and ascending colon, nearly always accompany the abnormal appendices and are found if the examination is complete. (Attention is called to several of the radiographs illustrating this point.)

The transverse type usually points directly inward to the median line. Downward displacement of the cecum may carry it into such position that objectively it may seem to be of the ascending type and especially so if the distal end is adherent.

In this classification I am attempting to place each group with due regard to the classical McBurney's point, using this landmark as a centre of radiation and considering the appendix only as observed when the patient is lying horizontal, or in the position in which laparotomies are performed.

The fourth class can be broadly divided into four groups. The shape as observed with the x ray varies greatly. The radiograph is but a shadow of superimposed parallel planes and false conceptions of the shape and contour may be obtained if thorough familiarity with the relative values of the diffusion of the shadow cast by the various segments is not taken into consideration; the nearer the radiographed object is to the plate and the farther it is from the target of the x ray tube, the sharper the image, while that portion of the plate is propor-

served to lie anterior, others posterior or to the outer side of the ascending colon. The general complaint of these patients has been of discomfort when walking or being carried in a jolting vehicle. In the horizonal position the appendix is relaxed and looped or sometimes doubled on itself; this depends upon the degree to which the cecum recedes upward. The tip alone may be adherent or the entire shaft involved in a mass of adhesions. When these patients are in the erect position the cecum drops, traction occurs, and the appendix is extended to its full length. Difficulty is usually experienced in radiographing the patient standing, because the dropping down and inward rotation of the cecum and ascending colon causes the appendix to be overshadowed. Any attempt to displace these structures by manipulation is difficult because of the muscle tension of the abdomen and the massing together of the abdominal contents.

The descending appendices are generally found to be normal. If adherent or deformed in any way they are more easily manipulated and radiographed because of their freedom from the influence of the larger cecum and ascending colon, and the fact that the ileum posteriorly forms a firm background and decreases the anterior posterior depth of the abdominal cavity. Many of this type are found adherent at the tip, accompanied by a somewhat immobile cecum which does not descend very far; this latter condition may be accounted for in several ways, but the most rational explanation is that when the cecum is retained in a high position there is better drainage. The more abnormalities found in

Served by Dr. William Hayes. Ap. Appendix; I. ileum; C. cecum; A.C. ascending colon. This appendix was very large, easily palpated, nonfunctioning, and of the ascending type. With the patient erect it acted as a supporting ligament for the cecum. Its tip was adherent well up into the abdomen. The patient had been subjected to several years' medication for ulcer. His principal symptom was a persistent dragging pain near the median line close to the umbilicus.

Radiograph 8.—Mr. DeL. Referred by Dr. William Hayes, Ap. Appendix; I. ileum; C. cecum; A.C. ascending colon. This appendix was very large, easily palpated, nonfunctioning, and of the ascending type. With the patient erect it acted as a supporting ligament for the cecum. Its tip was adherent well up into the abdomen. The patient had been subjected to several years' medication for ulcer. His principal symptom was a persistent dragging pain near the median line close to the umbilicus.

Radiograph 9.—Mr. S. Referred by Dr. H. Austin Cossitt, Ap. Appendix; C. cecum; A.C. ascending colon; G. constriction; I. ileum. This appendix is adherent. It will be observed that there is a very small amount of bismuth distributed throughout the appendix. This is no doubt due to the appendix having been filled with feces previous to the administration of the bismuth. The day following this examination the entire appendix was very opaque. This illustrates how one superficial examination may cause us to overlook an appendix with a small quantity of bismuth within it, especially if well diluted with other material.

Radiograph

Radiograph 10.—Mr. A. Referred by Dr. Henry Eichorn. Ap; Appendix; Sq; sigmoid; T.C. transverse colon; C. cecum. This very long irregular appendix adherent at the tip, is nonfunctionating, and of the movable descending type. The tip is adherent to the sigmoid. The sigmoid is unusually long. It passes upward to the right of the cecum to a point near the hepatic flexure, where it is adherent, then drops down and swings across the abdomen below the transverse colon to the splenic flexure. This unusual case will be reported in another group.

Radiograph 11.—Dr. D. Referred by Dr. William Hayes. Ap; Appendix; C. cecum; Ca; constriction; U. umbilicus. This appendix is of the ascending type, is adherent to the cecum and ileum, resting on the inner wall of the cecum to which it was firmly bound.

Radiograph 12.—Mrs. K. Referred by Dr. Austin Cossitt. Ap; Appendix; C. cecum; A.C. ascending colon; Sq; sigmoid; T.C. transverse colon. In this case several examinations were made and the position of the appendix determined, but the retention of the bismuth in the cecum and ascending colon prevented radiographing the appendix, as it was attached to the ascending colon in such a way as to fall in line with it. Following the administration of an enema containing the opaque salt the cecum and ascending colon was partially cleared of their contents, when peristalsis carried the enema into the transverse colon it will be observed that the peristaltic wave has almost reached the splenic flexure. This permitted the appendix to come in view. As outlined it can be seen passing upward on the inner side of the cecum and onto the anterior wall of the ascending colon. This appendix is a nonfunctionating, ascending, movable, and club shaped type.

tionally diffused and rendered dull in contour. Stereoscopic studies of a long distorted appendix may be of material aid in determining its exact relations to the surrounding structures.

An appendix which is objectively straight when observed under the fluoroscope or by the radiograph may be kinked or partially obliterated and, unless it contains bismuth or an opaque salt throughout its length or may be moved by manipulation so as to bring the kink or curve to a right angled plane with the x-rays, may be regarded as one without abnormalities.

A curved appendix, if the entire length can be observed, when found to be of uniform contour and functionating, may be considered as normal, although we must keep in mind the probability of its shape being influenced by the drop of the cecum when the patient is erect; this point impresses the

fact on our mind that the ptosed and mobile cecum may throw an appendix into an unfavorable position or distort it and produce an acute angulation which would interfere with function.

The kinked appendix is usually pathological and appears as a short stump curling backward toward the cecum. Another type of the kinked appendix is that in which the tip is adherent in such a position that it may rest with its long axis at an angle
proved that this is possible under favorable conditions without the aid of the x ray. However, by its use we can promptly locate the appendix and be certain that the organ which our fingers outline is none other than what we desire to find. I have been very much impressed with the deceptive character of bands of the abdominal facia, or bands of adhesions, and thickened intestinal walls in their tendency to give one the impression that he had his finger on what appeared to be a structure, about the size and consistency of the appendix—most deceiving unless these are excluded.

The first thing we should observe when palpating the abdomen for the appendix is the necessity of locating the cecum; this segment of the bowel in the greater proportion of cases is readily palpable and usually lies above the brim of the pelvis. We pass our hand downward until the end of the cecum slips upward under the fingers, this almost always presents us with an outline of that portion of the cecum to which the appendix is attached. Placing a finger over the sulcus which is produced by the longitudinal band of muscles we may palpate the base of the appendix. Once located at least seventy per cent. of appendices can be palpated; then if the opaque material has entered this structure we can readily see what we are hoping to find. The determination of its condition, size, and shape follows. A large number of subjects have a mobile cecum which, if not adherent up in the abdomen, drops into the true pelvis when they are erect and, even if not adherent within the pelvis, is very difficult to retract upward when the patient is placed in the Trendelenburg position. Frequently a ce-

with the common position of the shaft. If this occurs a shifting of the viscera may decrease the degree of angle or straighten the kink. (A type is illustrated.)

In the club shaped appendix the greater diameter of its cavity at the tip presents the appearance of a small ball of the opaque salts at the end of the shaft.

The looped appendix may be of considerable length. Several have been found with two or three loops and apparently six to ten inches in length, although the exact measurement is difficult to determine because of its numerous curves. These appendices are not necessarily diseased and their exact position is oftentimes difficult to determine. The length of time they retain the bismuth, the mobility, the diameter, and the degree of tenderness are determining factors in diagnosing their acute condition.

In all x ray examinations due allowance must be given for modifying factors such as the thickness of the abdominal wall, sensitiveness of the patient to palpation and manipulation, gaseous distention, scars, tumors, etc. One who is familiar with the physical examination of the abdomen knows well the influence that these conditions have on the manipulation of the viscera. The x ray enables us to locate the appendix and then, if permissible, aid in moving it about or placing the hand on it in such a way as to palpate its various segments. The size of the appendix naturally places restriction on the degree to which we can perceive its outline by the sense of touch. The well known skill of several able surgeons who have amply demonstrated the feasibility of palpating this structure has clearly proved that this is possible under favorable conditions without the aid of the x ray. However, by its use we can promptly locate the appendix and be certain that the organ which our fingers outline is none other than what we desire to find. I have been very much impressed with the deceptive character of bands of the abdominal facia, or bands of adhesions, and thickened intestinal walls in their tendency to give one the impression that he had his finger on what appeared to be a structure, about the size and consistency of the appendix—most deceiving unless these are excluded.

The first thing we should observe when palpating the abdomen for the appendix is the necessity of locating the cecum; this segment of the bowel in the greater proportion of cases is readily palpable and usually lies above the brim of the pelvis. We pass our hand downward until the end of the cecum slips upward under the fingers, this almost always presents us with an outline of that portion of the cecum to which the appendix is attached. Placing a finger over the sulcus which is produced by the longitudinal band of muscles we may palpate the base of the appendix. Once located at least seventy per cent. of appendices can be palpated; then if the opaque material has entered this structure we can readily see what we are hoping to find. The determination of its condition, size, and shape follows. A large number of subjects have a mobile cecum which, if not adherent up in the abdomen, drops into the true pelvis when they are erect and, even if not adherent within the pelvis, is very difficult to retract upward when the patient is placed in the Trendelenburg position. Frequently a ce-

with the common position of the shaft. If this occurs a shifting of the viscera may decrease the degree of angle or straighten the kink. (A type is illustrated.)

In the club shaped appendix the greater diameter of its cavity at the tip presents the appearance of a small ball of the opaque salts at the end of the shaft.

The looped appendix may be of considerable length. Several have been found with two or three loops and apparently six to ten inches in length, although the exact measurement is difficult to determine because of its numerous curves. These appendices are not necessarily diseased and their exact position is oftentimes difficult to determine. The length of time they retain the bismuth, the mobility, the diameter, and the degree of tenderness are determining factors in diagnosing their acute condition.

In all x ray examinations due allowance must be given for modifying factors such as the thickness of the abdominal wall, sensitiveness of the patient to palpation and manipulation, gaseous distention, scars, tumors, etc. One who is familiar with the physical examination of the abdomen knows well the influence that these conditions have on the manipulation of the viscera. The x ray enables us to locate the appendix and then, if permissible, aid in moving it about or placing the hand on it in such a way as to palpate its various segments. The size of the appendix naturally places restriction on the degree to which we can perceive its outline by the sense of touch. The well known skill of several able surgeons who have amply demonstrated the feasibility of palpating this structure has clearly proved that this is possible under favorable conditions without the aid of the x ray. However, by its use we can promptly locate the appendix and be certain that the organ which our fingers outline is none other than what we desire to find. I have been very much impressed with the deceptive character of bands of the abdominal facia, or bands of adhesions, and thickened intestinal walls in their tendency to give one the impression that he had his finger on what appeared to be a structure, about the size and consistency of the appendix—most deceiving unless these are excluded.

The first thing we should observe when palpating the abdomen for the appendix is the necessity of locating the cecum; this segment of the bowel in the greater proportion of cases is readily palpable and usually lies above the brim of the pelvis. We pass our hand downward until the end of the cecum slips upward under the fingers, this almost always presents us with an outline of that portion of the cecum to which the appendix is attached. Placing a finger over the sulcus which is produced by the longitudinal band of muscles we may palpate the base of the appendix. Once located at least seventy per cent. of appendices can be palpated; then if the opaque material has entered this structure we can readily see what we are hoping to find. The determination of its condition, size, and shape follows. A large number of subjects have a mobile cecum which, if not adherent up in the abdomen, drops into the true pelvis when they are erect and, even if not adherent within the pelvis, is very difficult to retract upward when the patient is placed in the Trendelenburg position. Frequently a ce-
cum which rests in the pelvis is distended with feces and literally wedged within this cavity and all efforts to remove it are in vain, but digital pressure from below may aid us in dislodging it. Occasionally a cecum so placed may be forced upward by the administration of a small enema, the rectum becoming distended it forces the colon upward.

The movable appendix may be readily displaced over a great area; this is proportionate to the length and condition of the mesentery of the appendix, together with the mobility of the cecum. The mobility of an appendix has a certain bearing on our interpretation of its condition but does not necessarily prove that it is not pathological, although, if mobile and functioning it can then be considered normal.

If the appendix is of the chronic type the muscular coat having been destroyed by inflammatory processes leaving the remaining tissue a flexible and hollow tube not able to properly discharge its entire contents, a residue of the feces containing the opaque salt may remain even after position or other conditions have partially drained the canal.

As the entire canal of the appendix is not of uniform calibre we do not expect to find on the screen or radiograph a symmetrical shadow outlining it in its due proportions. The bismuth salt may be retained in any segment of the canal. Very small particles may be distributed throughout its entire length mixed with feces which have entered the appendix previous to the administration of the bismuth; this results in small segmented shadows, the general distribution of which correspond to the location of the appendix. As observed in an accompanying radiograph it may be somewhat evenly distributed in segments which suggest a string of sausages. (See Dr. J. T. Case.)

The adherent appendix is not always fixed in its position while it may be adherent to the cecum, ileum, or its mesentery; at the same time it can be freely moved about with these structures. On the other hand a fixed appendix is adherent to the abdominal wall or bound down by numerous adhesions involving all the surrounding intestines.

The soft tissues which compose the wall of the appendix, with a few exceptions, do not cast a shadow. The writer has had two cases in which the wall of the appendix was of sufficient density to cast a shadow which could readily be seen. The difficulty of reproducing the shadow of the soft tissues in half tones prohibits demonstrating them in published radiographs. In the original radiograph it will be observed that there is a very thin line, pointing downward from the cecum, which is the opaque material. When the soft tissues can be seen in the radiograph they should be regarded as a deposit of scar tissue which has replaced the normal appendix and is evidently due to a chronic inflammation.

A number of patients with chronic appendicitis reacted very quickly to manipulation of the right side, and the abdominal wall at once became very rigid. Usually fat individuals or those with a persistently rigid abdomen are very hard to examine and, while with the fluoroscope we may see what we believe to be the appendix yet we are unable to palpate the organ.
My routine practice consists in the examination of the entire alimentary canal and extends over a period of from four to six days. As a rule the appendix is found to contain bismuth on the second day or at the end of the thirty hour period. There are so many exceptions to this that we should not make it a practice to depend on the time factor. My practice is to expect the appendix to be filled with bismuth any time after six hours.

FILLED BY MASSAGE.

This routine examination elicits all the anomalies which occur and enables the examiner to report very definite findings especially if sufficient time is taken with each case. The total time spent by the examiner with each patient is approximately five hours. The subject is examined from seven to twelve times. This may appear to be excessive, but a correct finding can only be made by close attention to detail and inspection of each segment of the alimentary canal as the opaque salt passes from mouth to anus. At times one is tempted, and occasionally will be superficial in the inspection of a case that does not justify so much time and labor, but the valuable data obtained will reward the examiner and are a stimulus to do careful work.

The vast risk assumed by the examiner in the numerous fluoroscopic inspections that are demanded in following the bismuth meal, and especially in examining the right lower quadrant to determine the condition of the appendix and the presence of iliac kink, must always be considered.

One may determine the location of an appendix and state that it contains bismuth the usual length of time, and so conclude that it is the chronic type and, being satisfied with this, may fail to prove the presence of adhesions or other abnormalities.

The exceptional number of appendices observed in the cases examined leads the writer to believe it is very rare for an appendix to become obliterated to such an extent, as to prevent material from entering its canal. Some may take exception to this statement, but as long as an appendix contains a mucosa which secretes, drainage must be provided therefore although the canal may be very small, it exists, and is capable of receiving foreign material. Again, I have observed some appendices receive the bowel contents in but a portion of their entire length and with palpation have then demonstrated the entire canal structure. In these cases, when operated and the appendix compared with the radiograph, it will be found to be considerably longer than its shadow.

CONCLUSIONS.

1. When there is chronic constipation due to delayed or inhibited peristalsis the appendix is usually diseased.
2. In the differential diagnosis of the appendix the x ray is essential.
3. When the pathological condition of an appendix is suspected and there are few symptoms an x ray finding is essential.
4. When the appendix is tied up in a mass of adhesions an accurate finding of the appendix enables the operator to rapidly locate it at operation.
5. Accurate determination of conditions typifying appendicitis should be made before operation.
6. When there are obscure symptoms in the abdo-
men which cannot be traced to a definite organ an
x ray examination of the appendix may show that
it is adherent to some distant organ.

MOVEMENTS OF THE TWO HALVES OF
THE CHEST IN DISEASE.

By L. Napoleon Boston, A. M., M. D.,
Philadelphia,
Professor of Physical Diagnosis, Medico-Chirurgical College;
Physician to the Philadelphia General Hospital;
Pathologist to Frankford Hospital;
AND Joseph F. Ulman, M. D.,
Philadelphia,
Demonstrator of Physiology; Lecturer on Experimental Physiology,
Medico-Chirurgical College.

The facts obtained from the physical examination
of the chest in a variety of pulmonary and cardiac
diseases, abnormal maladies, and cerebral lesions
have for many years caused one of us (Boston) to
believe that an accurate record of the movements of
the two halves of the chest would furnish clinical
data of special interest. Considering the work al-
ready accomplished along this particular line, we
are now convinced that this field of clinical study
does furnish valuable evidence in connection with
selected cases as is shown by the accompanying
pneumograms. The object of this preliminary re-
port has been to determine chiefly (a) the difference
in the amplitude of the curves of the pneumogram
as produced by the respiratory movements of the
two halves of the chest; and (b) delayed movements
upon the side in which respiration was inhibited.

A correlative study of the pneumograms of the
two halves of the chest, renders immediately appar-
ent the fact, that organic lesions of the lung and
pleura, and both liquid and air in the pleural cavity
give unmistakable evidences through this method.
Our observations have been confined to the study
of patients in the Philadelphia General Hospital, where
it has been possible to make a careful physical ex-
amination of each patient before employing pneu-
ographic study; and in one case the autopsy find-
ings were confirmatory with regards to the exist-
ence of unilateral pulmonary and pleural lesions
(Case I).

Certain factors are to be taken into consideration
in the application of this method of study to gen-
eral clinical use; and while at present our apparatus
is too cumbersome for use outside of the hospital,
it is believed that this field of observations reveals
sufficient definite clinical information to warrant its
employment whenever possible. One of us (Ul-
man) is devising an instrument for this purpose.

Alterations in the pneumograms as the result of
excessive or diminished muscular development of
the chest, must be reserved for a later report, as
must also the influences exercised by abdominal
and cardiac affections and other special movements
of the chest.

In the cases thus far studied (with the exception
of that of hemiplegia) a variable degree of dyspnea
has been present, and in consequence of this we
must grant that the muscles of the glottis and those
of the nares (regarded as accessory muscles of res-
piration) have been active. When dyspnea obtains
in man, undue movement of the alæ nasi is invariably
present. The glottis is dilated at each inspiration
by the contraction of the posterior cricoarytenoid
muscles in cases of dyspnea. Both the foregoing
features provide a useful result in respiration, by a
reduction in the resistance offered to the inflow of
air.

The apparatus (Fig. 1) consists of (1) kymo-
graph, (2) two Marey tambours, (3) metal stand,
(4) two clamps, and (5) two pneumographs
(Modified Ellis). The pneumograph consists of a
rubber tube, eight inches long, distended by a spiral
wire spring. One end of the tube is closed, while
the other end has an opening attachment to connect
with rubber tubing (6) to the tambours. A byvalve
(7) is interposed between each pneumograph and
tambour to prevent rupture of the rubber mem-
brane of the tambour.

Changes in the air pressure in the pneumograph
is transmitted to the Marey tambours (2), which
writes the respiratory movements upon the smoked
paper on the drum of the kymograph (8), and pro-
duces the pneumograms (9).

The pneumographs (5) are held in position upon
the lateral parts of the chest by means of two small
chains (11). One connects them across the back and
the other across the front of the chest. Care must
be taken not to have the chains too tight, as this
will inhibit the respiratory movements of the
chest. They are best applied on a level with the
sixth ribs so that the anterior part of the pneu-
ographs, which contain the opening for connections
to the tambours, is situated about the nipple line.
The distance separating the pneumographs over the
back will vary greatly, depending upon the size of
the chest.

The apparatus can be applied to the patient
whether in the erect, sitting, or reclining posture.
Have the small byvalves (7) open to prevent undue
pressure on the tambours while adjusting the appa-
ratus, preparatory to taking tracings. When ready
to take the tracings these byvalves are to be closed.
White glazed paper, six inches wide, is placed on
the drum (8) of the kymograph and smoked evenly,
though not too heavily, by the flame from a coal
oil lamp or a gas burner.
Be careful to bring the writing points of the two levers (10) of the tambours in the same vertical line, and with just sufficient pressure against the smoked paper, on the drum, to prevent binding. The distance between the two levers is not constant, but depends upon what type of tracing you desire to take. Usually from one and one quarter to two inches apart will suffice. The tension of the rubber membranes of the tambours (2) must be equal. Should the patient cough (Case V), yawn, sneeze, or laugh during the taking of the record, these acts cause undue amplitude in the curves of the pneumogram. Figure 2 shows the separate parts of the apparatus.

The time marker can be placed at the base of the drum and this record may be made at the time the respiratory movements are recorded (Fig. 6). The time record may be taken after the pneumogram, but in such cases care must be taken that the speed of the revolving drum is the same as it was when the pneumogram was made.

The degree of pressure within the pneumographs is increased by inspiration (causing the downward curve of the pneumogram), while expiration lessens this pressure and corresponds to the upward curve of the pneumogram.

Case I. A. F., aged sixty-three years; American; plumber by occupation; was admitted to the hospital July 30, 1913.

Past Medical History: Had a chance at the age of eighteen years, and paralysis of the right arm at fifty-five years, from which he completely recovered within a few weeks.

Present Illness: During the past four months he suffered from dyspnea on exertion. He noticed that his feet and ankles were swollen during that time. He experienced paroxysmal attacks of dyspnea which were accompanied by cough and slight expectoration. Vertigo was an annoying symptom throughout the course of his illness.

Physical Examination: The lips, ears, and extremities showed evidence of cyanosis. The respiratory movements were rapid, forty a minute. There was some edema of the ankles, and the general evidences of emaciation.

Palpation: The pulse was irregular, though full and strong at ninety. Vocal tactile fremitus was increased over the base of the left lung posteriorly.

Percussion: The note was impaired below the fifth rib posteriorly on the left. There was slight superresonance over the upper portion of the left and the entire right lung. The area of cardiac dullness extended three fourths of an inch to the left of the left nipple, and as low as the sixth rib. The right border of the heart as shown by auscultatory percussion, extended well beyond the sternum and into the epigastric region.

Auscultation: At the base of the left lung posteriorly there were to be heard a few fine, crackling rales, while over the fifth rib at the posterior axillary line, distinct bronchial breathing was audible. A distinct friction murmur was audible on a level with and one inch to the outer side of the left nipple. The heart sounds were weak and irregular as to both time and force.

During the second day after admission to the hospital Cheyne-Stokes respiration developed, which type of breathing persisted until death. The pulmonary processes of the left lung spread gradually until approximately one half of the organ was involved. The accompanying pneumograms were made the second day of the patient's stay in the hospital, and when the pulmonary process involving the left lung extended to a level with the top of the fifth rib. The pneumograms (Fig. 3) illustrate the distinct differences between the movements of the two halves of the chest. The pneumographic study was made when the patient was resting upon his back, and when Cheyne-Stokes respiration was presented. A correlative analysis of these pneumograms rendered immediately apparent the great variation in amplitude of both the curves of inspiration and of expiration, and showed as it did a decided enfeeblement of the respiratory movements of the left side.

Autopsy: Right lung approximately normal. Left pleural cavity contained thirty c. c. of serous exudate. Left lung presented the characteristics of pneumonia, stage of gray hepatization. The heart was markedly dilated and showed rather extensive myocardial changes. Other autopsy findings were of such a nature as to be of little or no interest in connection with the recorded movements of the chest.

Case II. J. Z., aged sixty-three years; Dutch Creole; admitted to the hospital March 18, 1913, for paralysis of the right arm and leg from which he had been suffering for the past two months. His mind was somewhat enfeebled and during the past few weeks he lost the power of speech. On August 20, 1914, the day on which the present study was made, the patient was able to move the right leg and arm, but was unable to walk and there was marked weakness of the right arm. The pneumogram (Fig. 4) was made with the patient sitting and shows clearly the effect of paralysis on the respiratory movements of the right side. When directed to inspire deeply the amplitude of the downward right curve exceeds that of the left curve, a feature due apparently to relaxation of the muscles of the right side.

Case III. T. R., aged thirty-seven years; white; male; was admitted to the hospital June 30, 1913, suffering from an attack of acute plurisy involving the left side. Upon physical examination it was found that both pleural cavities contained an abnormal amount of fluid, the dullness extending on the right as high as the fifth rib and to the top of the sixth rib on the left side. After three weeks' stay in the hospital, physical examination failed to

---

1The upper line in the pneumogram is from the right, the lower from the left lung. The beginning of the pneumogram is always on the right side of the cut.
reveal the evidence of fluid in the right pleural sac. At this time the left pleural sac was aspirated and thirty ounces of clear serous fluid was removed. The patient improved rapidly after aspiration and three weeks later (six weeks after admission) the accompanying pneumogram (Fig. 5) was made. The pneumogram served to show that the respiratory movements of both sides of the chest were abnormal, and that there was a decided irregularity in the respiratory curves, and further that there was appreciably more amplitude shown by the curves of the right side.

Case IV. H. S., aged fifty-six years; American; was admitted to the hospital July 23, 1913. Present illness began by chills and severe pain in the right side three days before admission. Upon entering the hospital the physical examination gave negative results except for a distinct friction murmur, heard best in the region of the right nipple.

The general symptoms, including a temperature of 103° F., were those of acute pleurisy. Three weeks after admission, and at a time when there were present physical signs indicating that a moderate amount of fluid was contained in the right pleural sac, the accompanying record was made. The pneumogram (Fig. 6) of the right side displays far less fluctuation in its curves than does that on the left, which tracing is also very irregular both as to amplitude and time. Thirty-seven ounces of fluid were removed from the right pleural sac immediately after making the pneumogram.

Case V. J. L., aged sixty-three years; born in England; eighteen years in United States; had been admitted to the hospital several times during the past year. He stated that two years ago he contracted a heavy cold and since that time he had had a severe cough which had been accompanied by free expectoration. Upon one occasion the sputum was blood streaked (tubercle bacilli present in sputum and feces). Physical examination disclosed the signs of a pulmonary cavity near the apex of the left lung.

The breath sounds over the left half of the chest were of the so-called cogwheel type. The accompanying pneumogram (Fig. 7) displayed a rather unique feature since the curves of the left side of this record never assumed the usual course, but were decidedly wavering throughout. Near the centre of the pneumogram the deep inspiratory depressions of the curves resulted from the patient's attempt to inspire deeply, and the upward amplitude of the curves, immediately following, resulted from a cough during forced expiration. It is noteworthy that after attempted deep inspiration and forced expiration the former rhythm of the respiratory movements of both sides of the chest were appreciably disturbed, and did not assume the usual course until after three or more respirations.

Case VI. M. J., aged forty-seven years; male; contracted a severe cold two years ago since which time he had been losing weight, and had had a severe cough accompanied by blood tinged expectoration. Sputum contained tubercle bacilli. Physical examination revealed positive evidence of a tuberculous cavity near the apex of the left lung. An x-ray study showed a cavity. The accompanying pneumogram (Fig. 8) taken with the patient standing, showed a decided lessening of the movements of the left half of the chest.

Case VII. W. D., aged sixty-five years; male; American; was admitted to the hospital July 10, 1913, for tuberculosis. Had influenza six years ago which was complicated by left pleurisy. During the past few months he had lost twenty pounds in weight. He suffered from extreme cough accompanied by expectoration, and pain in the left apical region. Physical examination revealed the existence of a tuberculous involvement at the upper portion of the left lung, the centre of which lesion was situated at the junction of the midclavicular line and the third rib. All the classic signs of a tuberculous cavity were present. The accompanying pneumogram (Fig. 9) showed that the portion of the left lung below the nipple, which was apparently healthy, caused greater movements of the left half of the chest than did the right lung which was emphysematous. When the patient was directed to inspire deeply the record showed his inability to expand the left side of the chest as freely as he did the right. (Fig. 9.) In other words, a tuberculous cavity located at the apex of a lung might give a record of undue expansion of that portion of the chest not overlying the cavity, while at the same time forced inspiration and expiration showed by the pneumogram that the movements of this half of the chest were limited.

Case VIII. T. R., aged fifty-three years; Italian; admitted to the hospital August 15, 1913. The physical examination showed marked distention of the abdomen and there were present the physical signs of ascites. The peritoneal cavity was aspirated and eight quarts of fluid removed. After the removal of the peritoneal fluid a physical examination showed the liver to be greatly enlarged; its lower border extending on a level with the umbilicus. The accompanying pneumogram (Fig. 10) was made two weeks after the aspiration, and at a time when the abdo-

Fig. 7.—Case 5. Bilateral pneumogram from a patient showing cavity at the left apex. Unusual amplitude of curves resulting from deep inspiration followed by cough.

Fig. 8.—Case 6. Bilateral pneumogram from a case showing a tuberculous cavity of the left lung.

Fig. 9.—Case 7. Bilateral pneumogram from a case showing tuberculous consolidation of the upper half of the left lung with compensatory emphysema of the right lung. Amplitude of downward curve results from deep inspiration and is followed by a succession of attempts at forced expiration. Dotted lines show that extreme expiratory effort of the right side occurred synchronously with inspiratory effort of the left side.

Fig. 10.—Case 8. Bilateral pneumogram showing characteristic differences in the curves from the two sides, resulting from ascites and hepatic enlargement. Dotted line shows delay in the downward (inspiratory) curves of record. "R."
men contained sufficient fluid to have given distinct fluctuation. The record showed unusual amplitude of the curves of both inspiration and expiration as the result of increased abdominal tension. The variation in the curves from the two halves of the chest probably depended upon the enlargement of the liver which will be seen to have materially altered the tracing of the right half of the chest, both as to amplitude and time.

**Fig. 11.**—Case 9. Bilateral pneumogram showing forced inspiration and forced expiration, and showing lessened amplitude of the curves of the record from the left side. No marked delay in the movements of the left side of the chest.

**Case IX.** J. O'D., aged forty-five years; American; treated in the hospital one year ago for a tuberculous lesion at the apex of the left lung. Admitted to the hospital August 5, 1913, at which time the physical examination showed impairment of the percussion note over the entire left lung, and there was distinct dullness above the third rib anteriorly. Both vocal tactile fremitus and vocal resonance were increased above the third rib anteriorly and at the left of the spine between the scapula. The expiratory murmur was prolonged and harsh and the voice sounds markedly increased over the area of involvement. The right lung and pleura were apparently normal. The movements of the chest as recorded by the accompanying pneumograms (Fig. 11) showed a decided inhibition in the amplitude of the left side curve, designating the act of inspiration from the left half of the chest.

**TUBERCULAR LEPROSY IN A NEGRESS.**

By J. L. Kirby-Smith, M. D.,
Jacksonville, Florida.

This case is reported to the profession on account of the fact that it originated in a community which is practically free from leprous infection, and in one having no history of exposure to the disease.

The accompanying photograph shows the extent of the facial involvement; the body and extremities are also involved to a considerable extent, but very few lesions show any ulcerations. Clinically the case is well developed, and typical of the more common form of leprosy, the nodular or tubercular type. Examination of the nasal secretions from superficial ulcerations in the posterior nares on two separate occasions showed the presence of the _Bacillus leprae_. The cutaneous lesions have existed for three years, the first to appear occurring on the face. In the past year they have greatly increased in number, and have been noticed on the body and the extremities. The following history was obtained:

**Case.** A. W., nubress, aged twenty-two years, married at seventeen years. Laundress. Born in Baker county, Florida, had lived in Jacksonville since a baby, and had never been out of the city. The patient stated that she always had good health, had had two pregnancies, one resulting in a miscarriage, and the other in a child which lived only three weeks. The husband of the patient was born in Georgia, and was always apparently in good health. Both parents of the patient were alive and showed no evidence of disease; both parents were born in Florida, and had never been out of the State. They had had twelve children, six of whom were alive and were apparently in good health, the others having died of ordinary causes.

Tubercular leprosy.

Treatment had not given any marked results. Chaulmoogra oil in increasing doses has been tried, i.e., thirty drops in milk three times daily. X-ray exposures caused slight improvement in the lesions on the face.

**THE USE OF THE X RAY IN THE DIAGNOSIS OF DISEASES OF THE CHEST AND ABDOMEN.**

By Logan Clendening, M. D.,
Kansas City, Mo.,
Instructor in Internal Medicine, University of Kansas.

(Concluded.)

**GASTRIC CANCER.**

In the last eight months I have had four cases of gastric cancer, examined with the x ray, which have come to operation. In three cases the diagnosis of gastric cancer could have been only tentative without the help of the fluoroscope. In every case the fluoroscope told us not only that a growth was present, but in what part of the stomach it was and its size. In all the cases the x ray diagnosis was confirmed in every detail at operation. The signs of cancer of the stomach by the x ray are "filling defects," so called, and abnormal gastric peristalsis. What filling defects signify can perhaps best be understood by the use of the diagrams in Fig. 8, which I have been using for the elucidation of the subject to students and physicians. Fig. 8IA is the diagram of a normal stomach; 8IB is that stomach as it appears on the fluoroscopic screen when filled with a bismuth meal. Fig. 8 II A is a stomach with a carcinoma growing into the lumen. 11B is that stom-
ach filled with a bismuth meal. The growth encroaching on the lumen of the stomach will be seen to break into the smooth contour of the normal bismuth shadow. This is called by röntgenologists a filling defect. (Fig. 9.) It seems hardly possible to me to exaggerate the importance of the fluoroscope in gastric cancer. If the early diagnosis of that condition is to be made at all at the present time, this method is by all means the most likely one to make it. It is worth emphasizing again that in most of the cases in which I have used the x ray there was no tumor, no visible peristalsis, no obstructive vomiting—they were cases in which the weight of the evidence was decidedly in favor of the gastric cancer, but which no man of experience would care to dogmatize about; yet anyone who saw the case with the fluoroscope would feel as sure that cancer was present as if he had been present at the autopsy. If there is a growth, even of small size, into the lumen of the stomach, or if there is sufficient infiltration of the stomach wall to stiffen it even over a small area, and so inhibit the passage of peristaltic waves in that area, or if there is a stenosis of the pylorus, the x ray will reveal it.

There are certain errors which may creep into the radiological examination of the stomach, as into every diagnostic method. In one case of salpingo-oophoritis many loops of small intestine had become adherent in the lower pelvis, and the pyloric end of the stomach had also been drawn down and was adherent; thus leading to the diagnosis of pyloric stenosis. In another case the diagnosis of pyloric stenosis was made because a bismuth meal remained in the stomach over eight hours, but gallstones were found at operation. On the whole, however, the x ray seems the most important means of examination we have in stomach cases. A good history is perhaps of most use, but the x ray is far superior to any other method now in use to confirm it. This does not mean, of course, that the physical examination and chemical examination of the stomach contents and stool need be discarded. We are not forced to any such choice.

Holzknecht (14), the pioneer in this work, has formulated some radiological symptom complexes of the stomach which are worth copying here. Like a good clinician, Holzknecht has not divorced the history and the physical and chemical examinations from his complexes.

Symptom complex 2: 1. No residue after six hours. 2. Marked defect in the gastric shadow. 3.
pars media. 4. Diverticulum without air bubble in the smaller curvature immovable. Diagnosis: Callo-
ous ulcer of the small curvature of the pars media.

Symptom complex 7: 1. Large sickle shaped bismuth residue after five hours. 2. Dilatation. 3. Loss of tone. Diagnosis: Old stenosis of the pylorus, due to ulcer.

Symptom complex 9: 1. No bismuth residue after six hours. 2. Marked defect in the shadow of the pars pylorica or pars media. 3. Transverse constriction of the gastric curvature. Diagnosis: Carcinoma on the basis of an old ulcer; no stenosis.

Symptom complex 10: 1. Stomach empty after six hours. Head of the bismuth column at the splenic flexure of the colon. 2. Shortening of the stomach. 3. Congestion of the cardia. Diagnosis: Carcinoma of the pars cardica.

Symptom complex 11: 1. Stomach empty after six hours. Head of bismuth column in ascending colon. 2. Stomach shadow normal. 3. Pressure point moving with the duodenum. Diagnosis: Ulcer of the duodenum.

Normal stomach: 1. Stomach empty in six hours. Head of bismuth column in the ascending colon. 2. Stomach shadow normal. 3. No increase of peristalsis. No antiperistalsis. 4. No sensitive pressure point. 5. Hydrochloric acid normal.

INTESTINE.

By the use of the bismuth meal, obstruction in the intestine can perhaps be shown better than in the stomach. So, for adhesions and tumors causing chronic obstruction, it is the most reliable diagnostic method we have. Enteroptosis also can best be dem-

---

Fig. 11.—Cecal constipation: taken one hundred and thirty hours after a bismuth meal.

Fig. 12.—Dyschezia, a bismuth meal has remained in the lower sigmoid colon four days.
there ever any retardment in the small intestine. We know of no authentic cause on record of chronic constipation in which any stasis was present in the small intestine. The cases of duodenal dilatation described by Jordan we have seldom seen. We have twice seen some obstruction in the terminal portion of the ilium (Lane’s kink), but in neither case were there symptoms analogous to chronic appendicitis. In most cases of constipation there is a stasis at some definite place in the large intestine. In about forty per cent, of the cases the stasis was in the cecum and ascending colon. The meal stays here from forty-eight to ninety hours after ingestion; in one case it remained five days. They have been described as cases of greedy colon. (Fig. 11.)

In a very small number of cases there was some obstruction in the transverse colon just before the splenic flexure was reached. Against all of one’s previous conceptions of probabilities, the transverse colon seems freer from stasis than any portion of the large intestine except the descending colon. By all odds, however, the greatest number of cases show the stasis in the lower part of the sigmoid colon. The colon here dilates to enormous size and the food residue stays here for days and sometimes weeks. This is the condition described by Hertz and named by him dyschezia. The rectal mucosa loses in the course of time all sensitiveness to the presence of feces; through disuse the call to defection no longer reaches the higher centres and the rectal and lower colonic musculature loses tone, and a pouch is formed. (Fig. 12.)

These studies are of use only to point the way to treatment. In the first place, it is worth while to consider for a moment the procedure of Sir Arbuthnot Lane. It will be noticed that the description given above of the normal large intestine in the erect position is not greatly dissimilar to his original descriptions of the anatomy of chronic intestinal stasis: its mere presence is no indication for operative procedure. The important thing, however, in considering the procedure of iliosigmoidostomy is that in a great majority of all cases of constipation the constipation is in the terminal part of the sigmoid colon. The operation of iliosigmoidostomy in these cases simply shuts off a portion of large intestine in which no constipation has ever existed, which the bismuth meal traverses in normal time, and throws the intestinal contents into the very portion of bowel which is the seat of the stasis. In a recent paper Mayo (16) states that in a number of cases of iliosigmoidostomy done for chronic constipation, the constipation was not cured. Is it not possible that some of these were cases of dyschezia? Bevan (17) in the shortest and sanest paper on the subject, warns against performing operations simply for chronic constipation alone, and strongly advises that in every case in which operation is performed definite evidence of adhesions and obstructive symptoms be produced; he feels that, for such a serious surgical operation as removal of the colon, definite evidence of organic obstruction should be demanded.

The treatment of the two main types of constipation, the cecal and the sigmoid, is relatively satisfactory. In the cecal type we have been using agar agar, one or two or three teaspoonfuls of the powder three times a day, and modifying the diet in the classical manner. In dyschezia the main attack has been centered on increasing the sensitiveness of the rectal mucosa, so that the call to stool will be obeyed. Cathartics are interdicted except that an occasional one, every two weeks or so, may serve a purpose. It is of no use to modify the diet of these patients. The main reliance has been placed on enemas, given at first twice daily, then once daily in the evening, and then at more infrequent intervals. Thus keeping the rectum empty, we increase its sensitiveness.

The education of the habit of going to stool at a regular time each day is equally important.

RIALTO BUILDING.

VAGITUS UTERINUS.

BY JOHN H. TELFAIR, M. D., New York.

Obstetrician to Fordham Hospital; Clinical Professor of Obstetrics in Fordham University School of Medicine.

Vagitus uterinus is probably the rarest accident that can happen to the parturient woman. In the last ninety-eight years, there have appeared about sixty-four papers on this subject, in the majority of which the authors give a detailed account of a case that happened under their immediate supervision. Up until about ten years ago, every paper on this subject aroused a storm of criticism: sometimes ridicule. This criticism was not limited to the profession in general, the bitterest usually coming from obstetricians of wide experience. These men were frank to say they never saw a case, and did not believe any one else ever did.

An analysis of the various reasons given by these critics against vagitus uterinus resolves itself into two fundamental propositions:

First. What is supposed to be vagitus uterinus is a sound produced outside the uterine cavity. In other words the observer is mistaken in what he hears.

Second. Air cannot gain access to the uterine cavity in sufficient quantity to support respiration.

I believe that both of these criticisms can be satisfactorily met. The physiological cause of vagitus uterinus must of necessity remain problematical, so with the exception of the presentation of a clinical case, all I may hope to do, is to advance some theories as to its origin.

The following case occurred during my service as resident physician at the Lyning Hospital, New York:

Case. Mrs. R., aged twenty-four years, para II, previous labor easy, no miscarriages, height 156 cm., weight
fifty-nine kilogrammes. All pelvic measurements normal. Labor started December 8, 1903, at 8 a.m. Thirty-eight hours later the patient had reached a stage of exhaustion with nothing accomplished. The usual means of accelerating pains and dilation were tried unsuccessfully. Pains had practically disappeared and the cervix had dilated to about the size of a silver dollar. As the fetal heart was becoming weak and irregular, I decided to deliver by accoucheur forceps, the cervix being soft and already dilatable. I was able by means of my hands alone to accomplish full dilatation in about twenty minutes. The head was in the right occipitoposterior position, unengaged; membranes unruptured. I did internal podalic version, the membranes rupturing when version was about half completed, or when the long axis of the fetus was at right angles to that of the uterus. At the time of rupture, my right arm was in the uterus up to the elbow. The left leg was brought down through the cervix, the foot projecting just outside the vulva. I had just grasped the foot loosely, preparatory to traction, when my assistant leaned over and flicked the sole of the foot sharply with his middle finger. The plantar reflex was immediately excited, and the child gave a prolonged cry. This was followed at once by two short, sharp cries. The cries sounded exactly as if the child were completely enveloped in a heavy blanket, and they were just as distinct. A hurried extraction was done at once, occupying in actual time less than a minute. The child breathed and cried normally without stimulation, and showed no signs of having inspired more than the ordinary amount of mucus. The weight of baby was 3,560 grammes. Owing to the rapid delivery, the cervix sustained severe bilateral lacerations which were repaired at once. The minister had an uneventful puerperium. The child acted normally, and on day of discharge weighed 4,000 grammes.

In a case of this kind, a subject which always arouses scepticism, corroborative evidence seems almost necessary. There were three other physicians present at the delivery, an attending physician and two of the house staff. These three men heard the cries distinctly, and no conference was necessary afterward for us to determine what they were or from whence they came. We all realized, unmistakably and at once, the source.

Before even the most superficial consideration of such a case, it is necessary to eliminate the possibility of error on the part of the attendant. Could a man of any experience mistake any other sound for the cry of a baby? Thorn, in his criticism of Sippel's case, attributed the sound to a vibrating fold of membrane in the vagina. To my mind, this does not deserve serious consideration, as may also be said of other theories advanced in explanation, such as, gas passed by the rectum, intestinal rumbling, etc. The cry of a baby is a definite thing; there is nothing that resembles it closely enough to cause confusion. For the production of crying in utero two things are necessary, namely, ruptured membranes and the presence of air in the uterus. In any operative procedure that necessitates the introduction of hands or instruments into the uterine cavity, it would be hard to exclude air. In the performance of low and median forceps operations, the vulva gapes, and the vagina is filled with air up to the presenting fetal part. The application of high forceps, or the performance of internal version, must necessarily be attended by the entrance of air along the side of the instrument or arm. It is not to be supposed that the tissues of the birth canal so closely approximate the arm or instrument as to prevent the entrance of air. Having entered along the side of the arm or instrument, it would penetrate to exactly the same point as the arm or instrument, be that point the lower uterine segment or the fundus. And air having once gained access to the cavity of the uterus, and having an avenue of communication still open between the uterus and the outer air, what is to prevent air from entering in sufficient quantity to fill all the interstices between the fetal trunk and small parts and the uterine wall. In other words the uterus is not a vacuum, and being in open communication with the outer world, the atmospheric pressure within the uterus must be the same as that of the outer air.

The argument might be advanced that in order to cause this inrush of air, there must be a time when there is a negative pressure within the uterus. There is such a time, and it is at the moment of rupture of the membranes.

With the membranes intact, and the normal amount of liquor amnii present, the uterine walls are everywhere in perfect apposition to the fetal envelopes, and there is no dead space anywhere. When the membranes rupture, the uterus contracts and readjusts itself to the shape of the fetus. After the escape of the liquor amnii, the uterus cannot so perfectly envelop the irregularly shaped fetal ovoid as it did the regularly shaped bag of waters. Between the ventral surface of the fetus and its small parts is space formerly occupied by liquor amnii. When this liquor amnii drains away, its place can be taken by but one thing and that is air.

It is not my contention that air, in this way, enters the uterus in every normal labor. I have simply endeavored to demonstrate that it is possible during operative delivery. And there are strong reasons why it should occur in operative and not in normal cases. The vertex presents in about ninety-seven per cent. of all cases at term. When the membranes rupture, the head, if not already engaged, comes down firmly into the cervix, completely filling its cavity, and preventing the escape of the after waters. It is certainly an average statement to say that when the membranes rupture, not more than half the total amount of liquor amnii escapes. The liquor that remains, must be in that part of the uterus where the uterine wall does not come in contact with fetal surfaces. This place is the space around and between the fetal extremities and abdomen. These spaces being filled by a dense medium, there is no negative pressure; no entrance of air.

Conversely, during operative delivery such as internal version, the membranes are ruptured with the hand in the uterus, the total amount of liquor amnii drains away, and that part of the cubic capacity of the uterus that is not filled by the fetus is immediately occupied by air. The presence of the hand and arm in the uterus by further separating uterine wall from fetal surface, enlarges this space. Given air in the uterus, one complete respiratory act would be sufficient to produce a cry. To provide a stimulus for that cry, it is necessary to compare the differences between intrauterine and extraterine life. It is sufficient for the purposes of this paper to say that the principal differences are the establishment of pulmonary circulation and respiration.

There are two theories as to the causes of the commencement of respiration; the stimulus of air on the skin and changes in the placental circulation.
The latter acts by the partial separation of the placenta, the resulting accumulation of carbon dioxide in the blood, stimulating the respiratory centre. Schwartz thinks that both are necessary for the establishment of respiration. Preyer maintains that stimulation of the skin only is necessary. Certainly it proved amply effectual in the case I have described, and at a time, too, when there could have been no interference with the placental circulation. The partial and complete separation of the placenta is accomplished by the marked diminution in size of the uterus which occurs immediately after the delivery of the child, and the subsequent rhythmic contractions, which by further diminishing the placental site, disintegrate the placenta by the formation of a blood clot. In my case, in which one leg only was through the cervix, there could not have been enough retraction to cause any separation of the placenta. The effect upon respiration of stimulation of the skin, flagellation, etc., is too well known to be more than mentioned. While placental circulatory change may occur and be a contributing element of beginning respiration, it is not a necessary element. The same cannot be said of stimulation, for we have seen a case where a pure reflex started respiration in utero. Of these two elements, it is easy to say which is the stronger. A consideration of the treatment of a badly asphyxiated baby will show that stimulation often succeeds where placental circulatory change has failed. Many babies whose placenta are delivered immediately after the birth of the trunk, do not cry until spanked vigorously. Were placental change necessary, or even a contributory cause, it certainly fails signally in these cases. It seems fair to state that stimulation of the skin alone is capable of starting respiration in the delivered child. It is also reasonable to suppose that the same agency that would act on the delivered child, would be capable of the same effect upon the child in utero. This stimulus acting upon the child in utero would result in the muscular acts of respiration, and presupposing the entrance of air, in true physiological respiration. A child that breathes in utero, even though it be but one inspiratory effort, is capable of at least one cry.

I have attempted to explain the means by which air enters the uterus. Its actual presence in the uterus needs no proof, for it is a sine qua non of vagitus uterinus, a subject that has been reported by competent observers too many times to admit of any doubt of its possibility. The necessary stimulus to respiration is furnished during operative procedures, the instrument or hand of the operator being the actual medium.

Of forty-four reported cases, more than half were operative deliveries; eleven being forceps, fifteen were versions, and one replacement of arm and cord. The fetal mortality of those cases was ten per cent., many of the surviving children living only after prolonged efforts of resuscitation. Vagitus uterinus is a possibility during any operative delivery, and once heard, the only hope of saving the child lies in a rapid extraction even at the expense of maternal lacerations and fetal injuries.

INTRAVENOUS INJECTION OF SALVARSAN AND NEOSALVARSAN.*

By Daniel Tucker Miller, A. B., M. D.
Terre Haute, Indiana.

The intravenous injection is now conceded by sphyllographers everywhere to be the most satisfactory method of administering salvarsan and neosalvarsan. Quite recently, though, many clinicians were decidedly in favor of the intramuscular method, and were using practically no other procedure in their employment of the drugs. However, this is only one of many instances showing the almost pathological rapidity of the changes and improvements now being made in medical thought, so that what is new and well established to-day is both old and utterly disproved tomorrow. Perhaps nowhere is this condition better illustrated than in the treatment of syphilis. Probably no other medical subject has received such an impetus for study and careful scientific investigation and experimentation as has this one, this impetus coming naturally as a result of many important discoveries relating to it, made during the last six or seven years.

Since the discovery of the Spirochaeta pallida and its establishment as the direct cause of syphilis by Schaudinn and Hoffman in 1905, and the finding

*Read before the Vigo County Medical Society, Terre Haute, Ind.

2 Marble Hill Avenue.
of the complement fixation reaction by Wassermann in 1906, it has become possible to diagnosticate this malady more quickly and accurately, and what is even more important, we are enabled to ascertain the extent of its advance in any individual in a way that was not at all possible before. The very late work of Noguchi and others on other tests for specificity, since Noguchi's discovery of the method of cultivation of spirochetes in 1911, and especially his work on the luetin test, gives promise of yet more important and simplified means to be placed in our hands for the estimation and control of this disease. Furthermore, the discovery of salvarsan by Doctor Ehrlich in 1910, and his later modification of this dihydrochloride into the sodium salt called neosalvarsan, has given to the medical profession one of the most marvelous exhibitions of the influence of medicaments over disease. Furthermore, it has shown all men that scientists may now work in conformity with certain chemical, bacteriological, and pathological laws, so that their researches may produce certain definite results. Scientific medicine no longer depends for its progress upon accidental chance or time honored tradition. Certainly the employment of this method of arriving at conclusions from scientific deductions based on proved data is the most hopeful thing for the advance of medicine in every way. It means a yet closer revision of our therapeutic armamentarium to those agents capable of withstanding pharmacological demonstrations as to their efficiency and the discarding of hundreds of drugs now commonly used. Ultimately, empirical therapeutics will be discontinued, of course.

But as to salvarsan and neosalvarsan: Many capable workers believed these drugs to be suitable only for certain selected cases, usually those not amenable to the old treatment of mercury and iodides, or at least only those which seemed very refractory to this kind of treatment. My opinion is that salvarsan, or preferably neosalvarsan, should be given to every case of syphilis, excepting those where it is positively contraindicated by very serious organic involvement of vital tissues. These contraindications will be discussed later. And the neosalvarsan injection should be repeated until the Wassermann test is negative and remains negative for a period of one or two years or even three years. So long as the reaction is positive it is justifiable to repeat the injection every thirty days, or in severe cases even more frequently. In every case the use of mercury by injection or hypodermically is to be advised as a succeeding treatment after the neosalvarsan. This does two things, both salutary for the patient's welfare. First it prevents his acceptance of the all too prevalent conception that one injection of neosalvarsan cures all cases of syphilis permanently. Second, it secures the really powerful action of mercury in its best forms. With this treatment always include insistent orders as to hot baths and you may serve your patient just as well as if he or she were at any famous bath resort. Finally, do not give iodides until the patient has had at least one year, or preferably two, of the arsenical and mercurial remedies. Iodides are most probably beneficial owing to their eliminative and resolvent action, and are not fitted for the beginning germicidal action needed during the first stages of the disease.

In those cases in which the nervous system is involved the administration of small doses of salvarsan, cautiously administered with the patient under constant watch, and repeated frequently, has given some very satisfactory results. Fordyce has even tried seven injections in a case of general paralytic dementia, with marked improvement. If that disease, the prognosis of which Frederick Peterson characterized as "always death within a short term of years," if paresis yields, what may we not accomplish in other syphilities by a persistent and intelligent use of the drug?

It may be stated authoritatively, that occasionally a single injection of salvarsan cures syphilis absolutely. That this _therapie sterilisans magna_, which was Ehrlich's ideal, has been really accomplished, we feel sure. This is shown by clinical findings, constant negative Wassermann and other specific tests, and also reinfection of such cured patients. Under the old treatment complete immunization from a later infection of syphilis was taught. This we now believe was due to the fact that mercury only held the disease in abeyance in practically all these cases we thought cured. The luetin test, which for old longstanding cases, as in parasyphilitics, with cardiovascular or nerve tissue involvement, seems even more sensitive than the Wassermann, may yet more completely prove or disprove the absoluteness of a cure in any given case.

Certain, too, it is, that the earlier neosalvarsan is administered following the initial lesion, the more thoroughly efficient is its action. This gives the greatest reason for making every effort to establish a very early differential diagnosis and the institution of treatment long before the appearance of the secondary symptoms.

**CASE I.** A young man, F. B., came to me on April 2, 1911, one week after inoculation with the very beginning of a chancre, the first case in my experience. Serum obtained by deep scraping showed spirochetes by the dark field condenser, and by specimen stained with Giemsa's stain. The following day, April 3, 1911, he was given 0.6 gramme of salvarsan intravenously. With the exception of one month's inunctions, he had had no treatment whatever since his injection of salvarsan, although he was urgently advised to continue mercury. He showed absolutely no clinical evidence of syphilis since, twenty-nine months following the salvarsan treatment, and his Wassermann reaction was still negative in August, 1913.

While this case illustrates the efficiency of an exceptionally early injection, the value of the drug in old cases has been demonstrated to our satisfaction nearly as well.

**Case II.** G. H., male, aged forty-five years, had been treated for three and one half years with mercurial inunctions and iodides and later with intramuscular injections of salicylate of mercury up to the physiological limit. Despite the mercurial gingivitis and glossitis, severe palmar syphilides persisted on both hands. His work was that of a tin molder and the deep fissures were constantly bleeding and very painful, while the appearance was such as to bar him from the family table at mealtimes. On June 15, 1911, I gave him 0.6 gramme of salvarsan intravenously. His palms healed entirely in five or six days and had remained clinically perfect to date. He had had no Wassermann test and no subsequent treatment. Doubtless the man had established a tolerance of the organisms toward mercury, and the arsenical treatment effected a cure. At least it had held the disease in abeyance perfectly for the past twenty-five months.
Case III. B. G., young man under my observation occasionally since November 6, 1910. After the usual course of secondary eruption, he was placed upon vigorous mercurial inunctions and hot baths, and responded perfectly. Five months later, he reappeared, however, with a relapse after discontinuance of his inunctions, saying he knew he was not to blame, but that he "would rather die than continue such treatment." At this time he was emaciated, had severe glandular involvements, a wellnigh universal eruption, large sized mucous patches and a hemoglobin index of sixty per cent., and an erythrocyotic count of 3,300,000. The general condition was unusually severe, but I recalled a similar case under treatment in a great hospital in Philadelphia in 1908, not very dissimilar except in its greater severity, the patient actually died under the most efficient hypodermic mercurial treatment that could be administered in this institution. I was only surprised that those malignant cases of syphilis could endure the disease and the mercurial saturnation so long. Immediately, on March 22, 1911, I gave him 0.6 gramme of salvarsan intravenously. He made a net increase of thirty-two pounds in weight in a short time, and all clinical evidence of the disease vanished. A few days ago this patient was in my office, stated that he had again neglected to take treatment, had had none whatever for two months that he still felt well, ate well; skin and mucous membranes were unaffected, and his weight was normal. He stated that he "was cured" although a Wassermann test would probably have disproved his assertions.

Case IV. C. R. V., female, aged thirty-four years, complained in July, 1912, that she had been suffering from ulcérations and a stricture of the rectum for the past four years and had been operated upon three times for this rectal condition, one such operation having been for a fistulous tract. On admission, the diameter of the rectum was about one fourth of an inch, constant bleeding and purulent discharge exuding from anus and a severe ulceration of the tract extending to the sigmoid flexure. Pain was such that it prevented general anaesthesia for examination and on defecation the patient could not bear to pass stools. Weight eighty-two pounds. History of acquired syphilis fourteen years ago, with treatment by protoside of mercury tablets for three months, and iodides for a short time thereafter. August 1, 1912, 0.6 gramme of salvarsan was given intravenously and in three weeks patient gained fifteen pounds and the rectum improved as to discharge. By means of tallow candles inserted into rectum, patient herself dilated the stricture to three fourths of an inch. Ulcérations and defecation became nearly painless if stools were loose in consistency. September 23rd, under general anaesthesia, rectal sphincters and the heavy nodulatéd cicatrices of the traumatic and syphilitic strictures were excised. Since then, recovery had been uneventful except that occasionally in the fifth or sixth month, slight bleeding occurred. Her weight was normal, the size of the stool normal, defecation painless, and appearance wonderfully improved. The patient continued taking large doses of potassium iodide, and mercurial inunctions with hot baths until May, 1913. After thirty days' cessation of treatment an intravenous injeciton of 0.9 gramme of neosalvarsan was administered. The patient had steadily improved to normal condition and weighed 118 pounds with intestinal or rectal symptoms.

In my series of intravenous cases twelve patients have been given a second injection, and six of these, not because of recurrent symptoms but as a prophylactic measure. All patients have been advised to continue mercurial inunctions and potassium iodide following the salvarsan and neosalvarsan treatments, but I must say that many have failed to do it.

While it is undoubtedly a dangerous procedure to administer neosalvarsan to patients well saturated with mercury or iodides, and is also inadvisable to begin mercurial or iodine treatment immediately following an injection of neosalvarsan, nevertheless the combination of this new and old treatment seems to me just yet to represent the course of greatest safety for our patients.

Probably very few men are provided, as is Wechslern, with extensive bedridden material for careful investigation and control of cases treated only with neosalvarsan. But by this method only will the true status of neosalvarsan in the treatment of syphilis be established. In my last 120 cases neosalvarsan has been used with just as good results as the salvarsan and, certainly with much less of toxic symptoms in evidence. Since there seems to be a lack of agreement among clinics on this point, I may add that in only ten per cent. of those injected with neosalvarsan there has been nausea with emesis, and a still smaller percentage have exhibited an increase of one or more degrees in temperature. With salvarsan, it was the exception rather than the rule if a patient showed no gastrointestinal disturbance and more than fifty per cent. of the patients manifested an increased temperature. Therefore, I believe the newer remedy to be less toxic.

In three cases of tuberc, each receiving two injections of neosalvarsan, marked improvement of the ataxia resulted and also improvement in general health and increase in weight. Inasmuch as intensive mercurial inunctions were instituted in each case following the second injection, it is impossible to estimate the amount of permanency of the results obtained. However, practically all writers agree that relapses within from forty to ninety days usually occur in almost all parasyphilitics who have been benefited by neosalvarsan unless subsequent treatment is instituted.

As to contraindications: Ocular dangers from neosalvarsan are nearly a negligible quantity. Even in severe chorioidoretinitis, marked improvement has followed the use of the drug. Neosalvarsan in 0.9 gramme doses has been injected by me during July and August, 1913, into two patients having acute syphilitic iritis, which is, I believe, not a well established procedure. In addition, for these cases the oculist in consultation prescribed darkness, atropine solution, a five per cent. solution of sodium locally, and moist heat. Both patients received mercuric cyanide intravenously, seven days following the neosalvarsan. Both patients responded quickly and made perfect recoveries.

Advanced Bright's disease is prohibitive absolutely, also advanced myocarditis. The constitutional disturbances, nausea, vomiting, fever, etc., have been shown to be due mainly to protein matter in the distilled water. Therefore only fresh distilled water should be used in the making of the solution for injection. The patient will avoid these unpleasant experiences better, and it is probably safer if he or she remain in bed for from ten to twenty-four hours, and aperient waters, taken before the injection, are used freely. I have been in the habit of occasionally administering four ounces of olive oil the night before, and have secured good results from this method.

Far advanced involvement of the nervous system means extreme caution in the use of the drug, or positive contraindication. But we must recall For- dyce's experience with his pariesis patient.

Conclusions.

In conclusion allow me to point out that there are about 275,000 new cases of syphilis in this country.
every year; and there are probably nearly three million people, here in the United States, yet untreated or only partially cured of the disease. With the wonderful achievements recently made, the important questions yet to be solved, and the superabundance of clinical material at the command of every practitioner, may we not feel that this presents to us a very alluring field for work?

323-325 Rose Dispensary Building.

PHYSICIANS IN ENGLISH LITERATURE.

By John B. Neary, M.D.,

New York.

In the whole realm of English literature we find many contributors who were primarily of other occupations, notably the learned professions of law, medicine, and theology, and other walks of life, including journalists, artists, and architects, and also the navy and merchant marine, together with many miscellaneous occupations.

From the earliest times the profession of medicine has contributed some of the brightest stars in this firmament.

Sir John Mandeville was one of the first contributors to English literature whose works have survived. Mandeville was born in 1300, educated a doctor of medicine, and wrote an account of his travels; first in Latin, then in French, and afterward in English, although it is doubtful whether he had visited all the foreign countries which he described.

Thomas Browne, who was also knighted, was born in London in 1605. For many years Sir Thomas was a practising physician in England. His works, Religio Medici and Pseudodoxia, treat of miscellaneous subjects in a witty and learned fashion.

There is no record that John Locke ever practised, but he studied medicine at Oxford, where he received the degree of Bachelor of Medicine. Locke was the leading philosopher of his day, and one of the greatest English philosophers of all time. His Essay on the Human Understanding is a profound treatise.

For his personal influence upon some of the greatest writers of his generation Dr. John Arbuthnot is remembered, rather than for his contributions to literature. He was a Scotch physician, settled in London towards the close of the seventeenth century, and devoted himself to science, literature, and the practice of his profession. Pope wrote of him with gratitude and affection and addressed one of the most famous and best epistles to him. Swift said of him, “he has more wit than we all have, and his humanity is equal to his wit.” Doctor Johnson pronounced him “the first man” among the great writers of his age. He wrote several learned and scientific works, but his two works of satiric humor are best remembered. They are the Memoirs of Martin Scriblerus, a travesty on pedantic learning, and The History of John Bull.

Tobias George Smollett, whose life has raised an imperishable monument to his fame, was born in Britain in 1721, descending from an ancient and honorable family in Scotland. After pursuing his preliminary studies with diligence and success Smollett became an apprentice to an eminent surgeon and later accepted a position as surgeon’s mate and went to sea. He was present at the siege of Cartagena, lived some time in the West Indies, and then returned to London.

Doctor Anderson, his biographer, informs us that Smollett received a degree in medicine from a foreign university; however, his career as a physician in London where he settled was not a success, probably becoming discouraged and prematurely abandoning a profession in which success is proverbially slow. In his eighteenth year poverty prompted him to go to London to seek a livelihood. He failed to have accepted a tragedy of his own composition called Regicide. It was then that he entered the navy, where in a brief time he acquired such an intimate knowledge of the nautical world as enabled him to describe sailors with such truth and spirit of delineation, that from that time whoever has undertaken the same task has seemed to copy more from Smollett than from nature. His works, such as the Adventures of Roderick Random, Peregrine Pickle, and Ferdinand Count Fathom, while faithfully depicting human character, are sometimes coarse and vulgar. Doctor Smollett published books of travel, histories, and other works, but the most pleasing of his compositions is The Expedition of Humphry Clinker, one of the first great novels in the English language. This masterpiece was written shortly before his death, and while he was surpassed by others of his time in artistic attainment, yet his clearness and vigor of style has exerted a lasting influence on English fiction.

One of the most loved and pathetic figures in the world is Goldsmith, whose life and character seem so intensely human and companionable that we are first interested in the man who made the world better for having lived in it; and then in his literary works which have a perennial delight and freshness. To know Oliver Goldsmith is to love him, to strengthen our inclinations to goodness, to become more pitiful toward weakness and error, and increase our faith in human nature.

Oliver Goldsmith was Celtic in disposition as well as by birth; he was born in 1728. At school he was thought impenetrably stupid and grew up thickset and ugly; his face being disfigured from smallpox, and with his sensitive disposition and blundering manners he became the butt of his companions, a condition he could never entirely shake off. In his seventeenth year Goldsmith entered Trinity College, Dublin, as a sizar, or free student; and in return for tuition he had to do objectionable work which was very humiliating to his timid and sensitive nature. He found his tutor ill tempered and harsh, and some studies, especially mathematics and logic, were distasteful to him. Having once gained a prize of thirty shillings he gave a dance in his room to some young men and women of the city. This violation of the rules attracted his tutor, who hearing the sound of the fiddle rushed to the festive gathering, gave Goldsmith a thrashing and turned his guests out of doors.

After receiving his bachelor’s degree he returned to his home and spent two or three years in a de-
sultry way; and while ostensibly preparing to take orders was in reality spending his time in miscellaneous reading and rustic convivialities. His fondness for gay dress was a weakness throughout his life, and more than once exposed him to ridicule.

When the time for his examination to the ministry came he appeared before the bishop in scarlet breeches, and was rejected. Then followed a succession of undertakings and failures without parallel. He became tutor in a good family, and lost his position on account of a quarrel at cards. He then resolved to emigrate to America, and left for Dublin mounted on a good horse, having thirty guineas in his pocket. In six weeks he returned to his mother's door in a condition not unlike that of the prodigal son. Every penny was gone.

He explained that the ship on which he had engaged passage had sailed while he was at a party of pleasure. The ship had been waiting for a favorable wind, "and you know, mother," he said, "that I could not command the elements." His uncle, one of the few that had not lost confidence in him, gave him fifty pounds with which to go to London, for the purpose of studying law. On the way he met an old acquaintance who allured him into a gambling house; he came out penniless. He then went to Edinburgh, where he remained eighteen months studying medicine, but spent most of his time in convivial habits which often brought him into financial difficulties. He next set out for a tour of the continent, with one clean shirt and no money: ostensibly to further study medicine, but in reality, it is believed, to satisfy his roving disposition.

In his wanderings he learned but little of medicine, but gained an intimate knowledge of Europe, which he afterwards made use of in The Traveler. He passed through Flanders, France, Switzerland, Germany, and Italy playing "merry tunes" on his flute which often set the peasants dancing, and procured for him food and lodging. At Padua he is said to have taken his medical degree. On returning to London he became usher in a school, proofreader, and afterwards an apothecary's assistant, a position he gave up to invest in a second hand velvet coat and set up as a medical practitioner and, failing as a physician, became a hack writer. From this humiliating station he was lifted by force of genius alone. He began by writing for reviews and magazines and compiling easy histories. His career as an author may be said to begin with his first serious undertaking, entitled, An Inquiry into the State of Learning in Europe. The gradual recognition of labors brought him more pay, and the circle of his acquaintance widened and brought him the friendship of the most distinguished contemporary literary talent, including Johnson, Reynolds, and Burke. They were original members of the celebrated Literary Club which brought into intimate fellowship the choicest minds of the English metropolis. The humor, grace, and picturesqueness of his writings, with their Celtic tone of sympathy and chivalry, attracted the attention of his associates, and the guilelessness and amiability of his character lent a charm to his personality, that triumphed over his weakness and drew the best men to him in tender friendship. That same charm exists in his works, and with the possible exception of Addison, he is what Thackeray claims for him, "the most beloved of English writers." The lesson of economy he never learned, and in 1764 he was in the hands of the sheriff, for an overdue board bill. He then sent for his friend, the celebrated Johnson. "I sent him a guinea," says Johnson, "and promised to come to him directly, I accordingly went as soon as I was dressed and found that his landlady had arrested him for rent, at which he was in a violent passion. I perceived that he had already changed my guinea for a bottle of Madeira and a glass. I put the cork in the bottle, desired he would be calm, and began talking to him of the means by which he might be extricated. He then told me he had a novel for the press which he produced. I looked into it and saw its merit, told the landlady I would soon return, and sold it to a bookseller for fifty pounds. I brought Goldsmith the money and he discharged his rent, not without first berating his landlady in a high tone for having treated him so ill. But speedily relenting, he called her to share in a bowl of punch. The novel in question was no other than the Vicar of Wakefield, one of the most delicious morsels of fictitious composition," justly observes Sir Walter Scott, "on which the human mind was ever employed." The plot of this famous little classic is quite faulty, but it is unequalled for quaint humor and philosophical pathos; the purity and grace of its style and the exquisite simplicity of its delineations of simple types of rural character classes it as the most charming of those novels we call "idyllic" and assures its place in English fiction. This novel has a perennial freshness and, if read in youth, is delightful and of benign influence, and we may return to it with pleasure and for solace in maturity and old age.

Goldsmith made use of some of the knowledge he gained in his European roaming in The Traveller. The Deserted Village is a most graceful and touching poem. The Good Natured Man, and She Stoops to Conquer helped to make a new era in the English drama. There are no wittier plays, they are continually resurrected, and rank among the greatest comedies of the world. While struggling with his pen to pay his debts, and admitting that his mind was not at ease, the end came at the age of forty-six. While he lay dying, the stairs leading to his quarters were filled with poor wailing outcasts whom he had befriended. Goldsmith was buried in Westminster Abbey, where his epitaph declares that "He Touched Nothing He Did Not Adorn."

That young genius and inspired interpreter of beauty, John Keats, has enriched literature, with poems which are among the choicest productions of the English muse. Keats was a surgeon's apprentice, and afterwards continued his studies in the London hospitals, but never completed his medical course. He was twenty-three when Endymion was published. Other highly artistic masterpieces as Hyperion, The Eve of St. Agnes, and Ode on a Grecian Urn are also from his pen. He went to Rome for his health and died there in 1821 at the age of twenty-six.
In America the field of medicine has not been so prolific in giving writers to English literature as has England; but the name of Oliver Wendell Holmes, one of the best writers in the English language is inseparable from these two professions. Born in Cambridge, Massachusetts, in 1809, Holmes was graduated from Harvard Medical School in 1830, and soon after became professor of anatomy at Dartmouth College, and later filled the same chair at his alma mater. An edition of his poems appeared in 1850, to be followed by others. His *Autocrat of the Breakfast Table* abounding in witty and brilliant thoughts in prose with occasional poems, was followed by the *Professor of the Breakfast Table*, and *Over the Tea Cups*. In 1861 Doctor Holmes published *Elsie Venner*, *Guardian Angel* in 1868, and *Mortal Antipathy* in 1885.

The *Habitat*, and other poems in the Canadian dialect, are very popular. The late William Henry Drummond, the author, was for years a practising physician in Montreal.

There is a perennial delight and freshness in the *hymn* *Sweet By and By* that has caused it to be translated or adapted into almost every language employed in hymnody. The author was Dr. S. Fillmore Bennett; the words and music were composed in less than a half hour.

The monument contributed to Thomas Dunn English, M. D. by the Author's Club is a fitting and graceful tribute to a true poet. In the simple but touching lines of *Ben Bolt* he has written his own immortality.

Of the living medicoliterary men, Sir Arthur Conan Doyle and Silas Weir Mitchell are doubtless the most noted. The name *Sherlock Holmes* is known in about every home where the English language is spoken, and the popularity of the works of Sir Arthur Conan Doyle, its creator, is still on the increase. Several years ago in an address at the opening of a medical school in London, he related some of his earliest experiences in the field of medicine. This dates back to the days of the unqualified assistant now legislated out of existence, "which" says Doyle, "had most excellent results on the death rate." As an assistant in a country practice in rural England, serving on board ship, and military duties, especially in South Africa, are but some of his medical experiences, in fact, there are but few phases of medical life he has not tried. It was as a student in the Medical Schoo' of Edinburgh that he learned the first lessons in deduction from a teacher, who made interesting diagnoses by this method. Dr. Doyle, while the greatest writer of detective stories is also known as a playwright and traveler. Being an active practising physician and novelist has kept Dr. S. Weir Mitchell busy. He was born in Philadelphia in 1829, and is still a resident of that city. While one of the best known American novelists, he is also a neurologist of note. Despite the fact that Doctor Mitchell completed his eighty-fourth year last February, his latest novel, now being published, is in the usual easy and well rounded style dear to his readers. Undoubtedly he is now the Grand Old Man of American fiction.

From a physician to a writer of successful dramas has been the rôle of W. Somerset Maugham, the English playwright. Some of his productions have been very successful in the theatres of London and New York.

It has recently been announced that the new British poet laureate is Dr. Robert Bridges. He was born in England, and is in his sixty-ninth year. Doctor Bridges was educated at Eton and Oxford. On graduation he studied medicine at St. Bartholomew's Hospital, and has served on the medical staff of the Children's Hospital, and also of the Great Northern Hospital, London. Since 1882 Doctor Bridges has devoted himself entirely to literature, especially playwriting and poetry. His chief critical work is *John Keats, a Critical Essay*. He also published a volume on *Milton's Prosody*, and eight plays, most of them dealing with classical themes. Among literary men in England the appointment is distinctly popular.

No other class is so peculiarly adapted to depict the tragedies and comedies of real life as it is seen every day, as the medical practitioner; herein lies a fertile field the surface of which has been merely touched.

30 East Forty-second Street.

THE VALUE OF IMMUNIZED MILK AS A
PROPHYLACTIC AND CURE FOR
TYPHOID AND TUBERCULOSIS
INFECTION.

By JULIUS ROSENBERG, M. D.,
Margaretville, Delaware County, N. Y.

Typhoid fever and tuberculosis furnish the largest percentage of mortality and illness, in spite of all effort, liberal expenditure of money, and widespread knowledge of their cause and mode of infection, they present a serious economic problem to the individual, to the family, and to the State.

In this brief preliminary report of a research and investigation, I desire to call attention to results and discovered facts. I believe that their practical application will cause a decrease of mortality and illness of both diseases, especially with the cooperation of the authorities, physicians and the public.

A fair, thorough trial must demonstrate that an effective yet simple method to check the spread and reduce the mortality of tuberculosis, typhoid fever, and probably other diseases, and a valuable aid for their treatment has been found.

To discover a prophylactic or remedy for typhoid and tuberculosis was far from my mind, when about two years ago I resumed my long neglected laboratory work. I had hoped to obtain a remedy against hay fever (of which I am a sufferer), isolate the toxines from plants, which I believe to be the cause and, by inoculation, produce a protective serum.

While thus engaged I discovered that the milk of inoculated animals acquired antitoxic and bactericidal properties identical with and in no way differing from those of blood serum. The presence of agglutinins, precipitins, and bacteriolsins can be demonstrated by the usual laboratory tests. Thus it occurred to me that here was the long sought for
remedy to prevent and cure tuberculosis and typhoid infections. I am convinced that I was not mistaken, for every day I realize increasingly the importance of the discovery and that the universal immunization of milk producing animals, and the consumption of immunized milk will prove of great value.

Immunized milk, instead of furnishing a culture medium, is inimical and antagonistic to the growth of bacteria, owing to the presence of precipitins and bacteriolyisins. In case of accidental contamination the bacteria will become inert, before the milk reaches the consumer. Furthermore, the use of immunized milk as a food will produce a widespread passive immunity and protection against infection from other sources than milk. I have by experiment shown the presence of precipitins in immunized milk. The precipitation of solids, inclusive of bacteria, is caused by the presence of bacteria against which the milk has been immunized. This action is certain and unerring. The practical value of the presence of precipitins in immunized milk is that it is destructive to the invading bacilli and can not carry or cause infection.

An additional proof of the bactericidal potency of the milk is shown by the following experiment (the details are omitted):

Five c.c. of milk, immunized against tuberculosis, to which was added a loop of tubercle bacilli, were injected into the peritoneal cavity of two guineapigs. The animals remained well after a lapse of four weeks.

That milk from immunized animals can convey passive immunity, is demonstrated by an observation upon a litter of guineapigs. The mother had been immunized against tuberculosis, receiving injections every fifth day for seven weeks. Immunity of the mother against living tubercle bacilli cultures had been shown, but the litter of five, although never inoculated, acquired resistance against infection, which could only have been conveyed by the mother's milk.

The prevalence of numerous typhoid infections in different sections of the country and the assurance that immunized milk will prove a valuable aid in treating these cases, induces me to publish this preliminary report. In the near future I will publish an extensive and detailed description of experiments, the vaccines used, and the methods of inoculation.

CONCLUSIONS.

In closing I will review the results of my research and their practical use and value:

1. Cows and goats can be immunized against tuberculosis and typhoid fever without any ill effects.
2. During and after immunization the milk remains wholesome, differing in no respect from other milk. My family and myself have taken for months milk immunized against typhoid and tuberculosis.
3. The milk of immunized animals contains antitoxines and bactericidal substances, differing in no respect from those of blood serum.
4. The usual laboratory tests demonstrate the presence of agglutinins, precipitins, and bacteriolyisins.
5. Immunized milk is inimical and destructive to the microorganisms against which the animal is inoculated.
6. Immunized milk lessens the liability of infection, owing to its bactericidal properties and producing passive immunity.
7. It is useful and indicated in cases where passive immunity is desired, and subcutaneous injections are impractical and contraindicated.
8. Passive immunity and protection against infection is obtained by drinking the milk of immunized animals. The drinking of six ounces for five alternate days produces protection against typhoid and tuberculosis infection. The milk must be taken on an empty stomach.
9. The fact that immunized milk destroys the tubercle and typhoid bacilli and produces antibodies in the blood, clearly shows its indication and usefulness in cases of typhoid fever and tuberculosis. It should be used in every suspicious case, as it may abort an infection in its incipency.

Hospitals and physicians who desire to avail themselves of immunized milk and investigate its merits will be supplied by me on application.

Abstracts and Reviews.

A SHORT ACCOUNT OF THE ORIGIN AND SCOPE OF ELECTROCARDIOGRAPHY.*

by A. D. Waller, M.D., F.R.S.,

Director of the Physiological Laboratory; Member of the Senate and Governing Body, Imperial College, London University.

The initial recording of the electrical action of the human heart was made nearly thirty years ago, and, while the records then obtained were in general similar to those of the present day, the interpretation which I now place upon them was not definitely formulated, though the general idea was present in my mind. We may retrace our steps to give a clear idea of the development of the present conception of the information which is to be obtained from the recording of the electrical reactions of the heart.

Working with isolated contracting hearts, it was noticed that at the inception of a contraction there was a point of high electrical potential at the base of the organ, while the apex and ventricles were electrically negative in potential to this portion. Thus a current would pass from one potential region to the other and it could be recorded by means of suitable electrometers. The current always began with the high potential area at the cardiac base and with the low at the apex region.

With the knowledge that the body tissues were electrical conductors, the next step was to record the difference of potential between the base and apex of the contracting heart in situ. Bearing in mind the usual idea of the anatomical position of the human heart—lying diagonally across the middle line of the body with the base directed toward the right upper extremity and the apex in the opposite direction—it seemed that the two upper ex-

*Summary of a lecture delivered before the Harvey Society, at the Academy of Medicine, October 4, 1913.
tremities should reflect the differences in potential of the two ends of the heart. This they did strikingly.

A study of the different possible leads was then made, and many different persons and animals were examined. The body was divided into lateral halves by an imaginary line passing from the mouth to the feet, which are considered as a single point. With one pole of an electrometer in the mouth and the other at the right hand a slight difference of potential was found and the record was correspondingly weak. When the left hand was used with the mouth the record was strong, the difference in potential was great. These leads were named the right and left superior. If the foot, or the feet were taken as the central lead in place of the mouth, completing the circuit by the left hand gave a weak response, while with the right hand the response was strong, resembling the left superior. Of course the two feet, when placed separately in circuit, that is, when the circuit was made from one foot to the other, gave very little electrical reaction, being approximately in potential equilibrium. From the foot to either hand is termed a lateral lead. Now if the two hands be brought into circuit, the response is strong, like that obtained in the left superior lead, or even stronger. The three favorable, or strong leads, were then seen to be the left superior, the transverse (hand to hand), and the right inferior.

From these observations it became evident that means were at hand for the study of the angle of the current axis of the heart. Representing the middle line of the body as running from the mouth to the feet, in the case of a record giving the strong and weak leads as just described, the current axis would obviously lie along a line beginning above and at the right and crossing the middle line at an acute angle to pass downward and to the left. The term current axis is applied to this imaginary line, and represents a line connecting the initial point of high potential at the base of the heart with the point of least potential at the apex. It seemed right to suppose that the idea was correct that this electrical axis corresponded roughly to the anatomical axis of the heart, and a case of situs viscerum inversus was obtained and confirmed the belief, for the strong and weak leads were exactly the opposite of those normally found. The axis here ran from the left above to the right below, again making an acute angle with the middle line.

If one draw a hypothetical line through the point of intersection of the current axis with the middle line, and perpendicular to the current axis, this line will fall in a direction corresponding to the weak leads. It is the line of zero potential; and I have called it the equator. The superior and inferior favorable leads, on the other hand, correspond to the axis of current and have been termed the axial leads.

The electrocardiograms obtained from the strong leads give a large, positive first ventricular spike (q—r—s complex), while the first ventricular spike in the weak leads is small, or often negative. By the use of a standardized instrument—one which gives a deflection corresponding in extent to the number of millivolts of current—it is possible, by measuring the relative height of the spikes in car-

state what the significance of each letter is. I submit that the nomenclature should be to call the first wave—that due to the contraction of the auricle—the A wave, the second wave, the acute spike, the first ventricular wave or spike—V₁, and the third wave the second ventricular wave—V₂. By means of simultaneous records of the electrocardiogram and the heart sounds, it is possible to show that the first ventricular spike is a fraction of a second in advance of the first cardiac sound, while the second ventricular wave is likewise a fraction of a second in advance of the second cardiac sound. This nomenclature means something and does not unnecessarily tax the memory for the abstract. In the first ventricular wave should be included the entire complex now designated as the Q-R-S complex. I do not recognize the different slight deflections called Q and S as separate entities.

Before closing, it is important to indicate the effect that respiration has upon the electrocardiograms from the two types of heart so that the clinical observer may be able to discount these variations for what they are worth.

In the case of the cor longum et durum, with the cardiogram from the right superior lead, the amplitude of the first ventricular spikes is greatest in inspiration, and least in expiration, appearing with wavelike increases and decreases in amplitude. From the left lateral lead the cardiogram shows an effect just the opposite of that from the right. In the case of the cor brève et molle the entire complex of increase and decrease in the amplitude of the spikes is the exact opposite of that from the cor longum et durum. In both cases there are often to be noted phasic vagus alterations in the rate of the heart—slowing during expiration, quickening during inspiration.

My appeal is to the clinical observer, and I submit that the use of the electrocardiographic apparatus or of the oscillograph has become a valuable adjunct to our means of making more accurate diagnoses in cases of cardiac disease or disturbance. It is no longer a laboratory toy, or an apparatus of pure scientific physiological interest, but it is an instrument of great clinical value, and one of easy application. A last appeal for the adoption of the more rational naming of the several waves of the electrocardiogram will, I hope, bear some fruit among American physicians.

**Prize Essays.**

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXXXVIII.—How do you treat insomnia? (Closed September 15th.)

CXXXIX.—How do you treat chancreoids? (Answers due not later than October 15th.)

CXI.—How do you treat the symptoms of senility, without organic disease, but showing approaching dissolution? (Answers due not later than November 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the JOURNAL. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXVII was awarded to Dr. W. C. Hess, of Cresco, Iowa, whose article appeared on page 673.

**PRIZE QUESTION CXXXVII.**

THE TREATMENT OF THREATENED ABORTION.

(Continued from page 675.)

Dr. Nelson Du Val Brecht, of Washington, D. C., says:

The therapy of threatened abortion resolves itself into the prophylactic and curative. The preventive treatment is applicable to those cases where repeated abortions have occurred (the so-called abortion habit). The obstetrician having ascertained this fact from the anamnesis, or previous history of the patient, should seek diligently for the cause and endeavor to remove it if possible.

Prophylaxis.—After the cause of miscarriage has been discovered in patients who suffer from the habit, the prophylactic treatment indicated should be instituted from the date of conception or several months prior to that event. One of the commonest etiological factors in the production of abortion is undoubtedly syphilis. If lues is suspected to exist in either parent, a Wassermann or Noguchi reaction should be made, and a thorough course of antisyphilitic treatment should be insisted upon if the test is positive, and continued until the test becomes negative. One or more doses of salvarsan (arsphenolaminhydrochloride), from four and one half to six grains, should be administered intravenously, intramuscularly, or subcutaneously. This should be followed by the use of the iodides and mercury. The following formula is useful if the stomach is retentive and does not rebel:

<table>

M. ft. pilula No. j.
Sig.: One pill, three times daily, after meals.
Inunctions of mercury, with potassium iodide by
the mouth, are usually better borne.

If displacement of the uterus exists the organ
must be restored to its normal position, and held in
place by a suitable pessary until its increased size
will prevent a repetition of the malposition. Re-
troflexion and retroversion especially should be
corrected by gentle manipulation, posture, and a
pessary. Diseases of the womb and annexa should
be treated before conception occurs.

When no specific cause can be found and an irri-
table condition of the uterus is supposed to be
present, the patient must be kept quiet and in bed,
especially at the time when menstruation would
normally occur. She must be guarded against
fright, nervous shock, and over exertion, and sexual
intercourse must be interdicted; nerve sedatives
as the bromides, viburnum prunifolium, and potas-
sium chlorate should be given.

Treatment of the attack.—If the hemorrhage is
slight, the os uteri not much dilated, the mem-
branes intact, and the fetus alive, "every possible
measure should be used to continue the pregnancy
to full term. The patient should be put to bed in
a cool, dark room, with light bedclothing, and be
maintained at absolute rest, not even leaving the
bed for the purpose of micturition or defecation.
Medicinally, opium and its preparations are our
sheet anchor to secure mental and physical rest, and
to check hemorrhage and inhibit uterine contra-
tion. The liquor opii sedativus, twenty to thirty
drops every two hours; the tincture, ten to fifteen
drops, two or three times a day; or the acqueous
extract, one half to one grain, in rectal supposi-
tory, repeated as often as may be necessary to stop
the pains, may be employed. Hypodermic injec-
tions of morphea, one quarter to one sixth grain
are often efficacious, especially if a quick action of
the remedy is desired, and we wish the added ad-
vantages that the remedy does not cause nausea and
is not lost by emesis. Hypodermic tablets of the
morpheine salts combined with atropine are prefer-
able to those composed of the plain alkaloid.

The following formula is often useful:

R. Codein sulphatis, 8
Extr. hyoscymiani, 8
Extr. viburni prunifolii, 8
Oleum theobromae, 8

Fiat suppositorium No. 1.

Sig.: One every four to six hours, introduced within
the bowel.

To overcome the constipation caused by the op-
iates mild laxatives, as saline, caustor oil, solution
of citrate of magnesia, cascara sagrada, or simple ene-
mas of warm water, soapsuds, glycerin, olive oil;
or rectal suppositories of glycerin are indicated.
Chloral hydrate and potassium bromide, either
alone or in combination, may be used, when for
any reason opium is contraindicated. The drug
measurement may be augmented by the employment of
viburnum prunifolium (fluidextract, one drachm,
or solid extract, four grains in pill form, every two
or three hours), which acts as a valuable prevent-
ive of abortion, and quietens the uterine contractions.
From five to seven days after the disappearance of
symptoms, the patient may be allowed to leave the
bed, to which she should return promptly if the
hemorrhage or pain returns.

Contraindications.—The use of ergot, the tam-
pon, the ice bag, vaginal packing, or the application
of cold cloths to the lower abdomen, are positively
contraindicated. They all promote expulsion of the
fetus.

Dr. Irving Friedenreich, of New York, observes:

When called to a case of threatened abortion
it is a matter of great importance to be able to
differentiate threatened abortion from inevitable
abortion, because the treatment in the two con-
tions is diametrically opposite.

It is inadvisable to examine a patient who threat-
en to abort because of the danger of exciting
uterine contractions or causing hemorrhage, unless
diagnostic purposes. Prophylactic treatment is
of great value. A patient who is pregnant should
not over exert herself with household duties. If
there is a retrodisplaced uterus it should be cor-
rected with a proper pessary. The bowels should
be regulated and kept open during pregnancy.
Syphilitic cases should be treated with antisyphilitic
remedies. Bright's disease, which may be a cause,
should be treated by proper diet, etc.

The main treatment consists in rest, physical
and mental. This is accomplished by keeping the
patient in bed in a dark, quiet room. The patient
should be given one quarter grain of morphine
to quiet her. Twenty minims of laudanum should
be given in addition by enema every four hours.

Or the following may be given:

R. Soda bromi, 8
Tinctura hyoscymani, 8
Fluidextractus viburni prunifolii, 8
Syrupur. aurantii dulcis, q. s. ad.

M. Sig.: Two teaspoonfuls every two hours.

Very often this treatment will suffice to check the
symptoms. Sometimes it will lessen the pain, but
the hemorrhage will continue. In such a case
how long will we allow the patient to bleed? If the
patient shows signs of anemia due to the hemor-
rhage, empty the uterus. If the bleeding does not
exceed the quantity of a normal menstrual flow no
worry should be entertained. Very often a slight
staining will continue for weeks. We further wish
to know if pregnancy still continues. This may be
found out by examining the patient at the end of
two weeks. If the uterus has increased in size the
fetus is growing. If there is no increase the fetus
is dead, and it is best to empty the uterus.

The bowels should not be moved for three days,
then one half ounce of caustor oil should be given,
and before the movement occurs inject a tablespoonful
of olive oil to prevent straining from the evacu-
aton of hardened feces. The bladder should be
attended to. If necessary, catheterization should
be resorted to under aseptic precautions. The diet
should be strictly liquid, consisting of beef tea,
milk, and chicken soup for the first few days.

If the loss of blood is excessive, hemorrhage may
sometimes be accomplished by the elevation of the
pelvis or by applying cold compresses to the vulvae.
Never tampon.

After five days, the patient may be allowed to get
out of bed, returning gradually to her work and
getting back to bed again as soon as she notices any staining. To summarize:

1. Rest—physical and mental.
2. Fluid diet.
3. Care of bladder and bowels.
4. Hemostasis: By elevating the pelvis and cold compresses to the vulve.
5. Empty the uterus if bleeding is severe.

Dr. Sterling O. Fields, of Newport News, Va., says:

One should endeavor to satisfy himself that the threatened abortion is not really some menstrual irregularity; a cessation and sudden establishment of the menstrual flow from other causes than pregnancy; or the efforts of an irritable uterus to expel a polypoid tumor.

The treatment of abortion should properly be begun before it is threatened. A pregnant woman must be cautioned against overexertion, jolts, or jars. Endometritis, tubal and ovarian infection, etc., demand treatment before impregnation. In cases of irritable uterus, rest in bed at the times corresponding to the menstrual epochs, supplemented by watchfulness against physical and nervous strain, will often prove effective. Syphilis in the mother calls for antiluetic treatment. A displaced uterus in pregnancy calls for restoration, the organ being retained in place by tampons or pessaries until its size is such as to prevent a recurrence. Cough, vomiting, and other spasmodic muscular movements demand appropriate remedies.

The active treatment of threatened abortion is comprised in the one word, "rest"—rest secured by the supine position in bed and the administration of drugs to decrease both the sensibility of the nervous system and the activity of the muscular system. The patient is kept in bed in a darkened and quiet room, receiving no visitors, and concerning herself with none of her household worries. Her diet should be liquid. Of drugs, opium deserves its reputation in such cases, women in this condition exhibiting a tolerance which often makes it possible to give unusual amounts. With opium, small dose of chloral and potassium bromide may be combined. Viburnum prunifolium is much used in these cases of threatened abortion, and the results amply justify its use.

The best routine method of treatment is probably the administration of 4 c.c. of fluid extract of viburnum prunifolium, three times daily, and the administration of 0.03 gr. of the extract of opium three times a day. This treatment is kept up until the practitioner is satisfied that all danger of abortion is over, or that abortion is inevitable. If the danger of abortion is warded off, the woman is allowed to resume her ordinary routine, subject to such restrictions as the physician may see fit to impose.

Dr. F. McKelvey Bell, of Ottawa, Canada, considers:

The treatment of threatened abortion as presenting two aspects: First, that during the emergency and, second, that for the prevention of a recurrence.

During the emergency: The patient should have absolute rest, mental and physical. She should be in bed, in the supine position with the hips slightly elevated. The room should be darkened and quiet—no visitors. A hypodermic injection of one quarter grain of morphine, combined with atropine, is given at once. This is more rapid and reliable than suppositories of opium powder (1 grain) and chloral hydrate (10 grains), which may be used subsequently every four hours if required, to prevent further uterine contractions and allay nervous irritation. Heat, by means of a hot water bottle, over the lower lumbar region will assist as a uterine sedative.

In those rare cases where opiates are contraindicated, and in all cases when the opiates have finished their work, as indicated by the cessation of pain and hemorrhage, it will be advisable to administer, by the mouth, a mixture containing fifteen grains of potassium bromide and one half drachm of fluid extract of viburnum prunifolium three times daily, after meals, the former to allay general nervous irritability, and the latter as a uterine sedative. The diet should be light.

Avoid the use of tonics such as quinine or strychnine, and stimulating glandular extracts such as epinephrin or pituitary extract, etc., which excite contractions of involuntary muscles.

To prevent recurrence: It may be necessary to keep the patient in bed weeks or, in rare cases, even months.

The immediate danger being past, look for the causative factor. It may be a habit of abortion, recurring with each menstrual epoch. If so, insist upon rest in bed for the several days corresponding to each period. If retrodisplacement of the uterus is the cause, use soft rubber pessaries or wool tampons for correction, until the uterus is sufficiently enlarged to lift itself out of the pelvis.

Such diseases as syphilis, diabetes, anemia, nephritis, etc., require appropriate treatment. Recurrent spasmodic affections, such as epilepsy, chorea, eclampsia, etc., if found, should be given attention. The albuminuria of pregnancy, which may be a cause, responds well to thyroid treatment. Excessive coughing or vomiting should be relieved. Advise patient to avoid all nervous excitement, especially coitus and undue exercise.

(To be concluded.)

Therapeutic Notes.

Treatment of Synovial Cysts at the Wrist.—J. Parowski, in Progrès médical for March 8, 1913, strongly recommends injections of tincture of iodine in this condition. An ordinary hypodermic syringe, with a short needle, is used. The back of the affected hand is painted with tincture of iodine, and the hand placed flat on a table, or allowed to hang over the edge in case it is necessary to render the cyst more prominent. The cyst being held with two fingers of the left hand, the needle is then quickly introduced. In nine cases out of ten none of the brownish jellylike material contained in the cyst appears through the needle. Two or three drops of iodine tincture are then injected and the needle removed. In case any of the cyst contents, mixed with the iodine, exude at this time, a little more of the tincture should be injected. A light
dressing is applied, which should not interfere with the movements of the hand or fingers, and left on for four or five days. The cyst will then have softened, shrunk, and sometimes even entirely disappeared. Another injection should then be given, and a light dressing allowed to remain for three days, after which the cyst will have been completely cured in ninety-nine out of 100 cases. No case resists a third injection.

Contrary to what has already been written of this method, there is but little pain—the passage of the needle through the skin is the most painful part of the procedure. In the succeeding hours the hand feels slightly hot and numb. A marked advantage of the method is that the hand need not be subsequently immobilized; it may, in fact, be employed in the patient’s customary work on the same day. The alleged danger of entrance of iodine into the wrist joint if the cyst should happen to communicate with the latter seems very remote. In the twenty-two cases in which the author employed the iodine method, no evidence of such communication could be observed. The jelly-like consistency of the cyst contents and the small size of the orifice of communication are also factors of safety in the injection method. The author has seen no recurrence in the cases treated. Simplicity and absence of scars are additional advantages of the procedure.

Treatment of Hay Fever.—Menier, in Journal de médecine de Paris for April 19, 1913, is credited with the recommendation that, in the hay fever paroxysm, the patient be given to inhale a four per cent. solution of menthol in chloroform, to be followed by a spray of one in 2,000 epinephrin solution.

For the ocular symptoms, in particular the photophobia, one may prescribe:

R Physostigmine sulphate, ....... gr. ½ (0.02 gr.);

Aque destillata, ............... 3iss (10 grammes).

Or.

R Picoline nitrate, ........... gr. ¼ (0.005 gr.);

Aque destillata, ............... 3iss (10 grammes).

Solve.

One drop of either solution is to be instilled in each eye.

In asthmatic forms, dyspepsia should be combated with antispasmodics. In light cases bella-

 donna and valerates are indicated.

R Extracti belladonnae foliorum, gr. ½ (0.005 gr.);

Extracti opii, .......... gr. ½ (0.02 gr.);

Syrupi simplicis, ........... 3x (40 grammes);

Aque laurocerasi, ........... 3iss (10 grammes);

Aque destillata, ............... 3iss (80 grammes).

M. Sig.: To be taken in one day.

Treatment of Constipation.—Phoebus, in Paris medical for March 15, 1913, is credited with the following formula of a laxative suppository:

R Sodi sulphatis exsiccati, ........... 3i (8 grammes);

Saponis albi pulveris, ........... 5v (16 grammes);

Mellis spissae, ............... q. s.

M. Plant suppositoria No. iv.

An electuary of sulphur for the treatment of habitual constipation might be prescribed thus:

R Sulphuris lotii, ............... 3i (30 grammes);

Potassii bitartratis, .......... 3ss (15 grammes);

Mellis albi, ............... 3ii (90 grammes).

M. Sig.: One teaspoonful once or twice daily.

Treatment of Idiopathic Unilateral Facial Spasm.—Henri Claude and Fernand Lévy, in Bulletins et mémoires de la Société médicale des hôpitaux de Paris, March 13, 1913, report a case in which injections of magnesium salts were employed with marked success. Their object in trying these agents was, while overcoming the spasm, to avoid every chance of subsequent facial paralysis, such as may result from injections of alcohol. The patient showed frequent and intense paroxysms of clonic and later tonic contractions of the left side of the face; each attack was accompanied by marked tinnitus in the ear of the same side. The condition was of two years’ standing. Injections of a twenty-five per cent. solution of magnesium sulphate were first made around the chief temporofacial nerve branches; but though the frequency and intensity of the attacks diminished, the spasm was not overcome. An injection of two cubic centimetres of a fifty per cent. magnesium chloride solution was then made around the facial nerve directly at its emergence from the stylomastoid foramen. A sensation of painful numbness was at once experienced locally, and on the next day there was slight swelling, but no facial paralysis nor noteworthy effect on the spasm. On the fifth day, however, the contractions were seen to be growing less frequent and weaker, and on the tenth day no spasmodic manifestation whatever remained. At the time of writing this condition had been maintained for over a month. If recurrence should later take place, the treatment, which is neither dangerous nor attended with much pain, could easily be repeated.

Treatment of Chorea.—R. Oppenheim, in Progrès médical for March 22, 1913, states that in mild forms of chorea the use of arsenic is unnecessary. Careful supervision of the diet, an increase in the period spent in bed, and sixteen hours, attention to the regularity of the bowel movements, and the giving of a general wash with hot water each morning, followed by dry rubbing, are among the measures indicated. Twice daily give a tablespoonful of the following mixture:

R Antipyrine, ............... 3iss (10 grammes);

Tinctura belladonnae foliorum, M. xl (2.25 grs.);

Syrupi aurantii florum, ........... 3i (60 grammes);

Aque destillata, q. s. ad. ........... 5v (150 grammes).

Misce.

In very severe cases of chorea, the child should be kept isolated and in a bed surrounded by padded boards. Arsenical treatment should be given, and likewise antipyrine in doses larger than in the quoted formula. If the antipyrine does not prove effective in a few days, chloral hydrate in full doses should be given:

R Chlorali hydratis, ........... 3ss-i (2-4 grammes);

Potassii bromidi, .......... 3v-4s (1-2 grammes);

Codeine sulphatis, .......... gr. 3/1 (0.04 gramme);

Syrupi, ............... 3v (20 grammes);

Aque destillata, q. s. ad. ........... 3iss (110 grammes).

M. Sig.: To be taken within twenty-four hours in tablespoonful doses.

Where infectious phenomena or cardiac complications accompany chorea, sodium salicylate in daily doses of from thirty to sixty grains (two to four grammes) should be added to these measures.
THE THERAPEUTIC USE OF THORIUM X.

The steady development of radioactive agents both as to the number available and as to their therapeutic value, has suggested the internal use of those whose physical structure permitted administration by the mouth, subcutaneously, or intravenously. Among these is thorium x, a product of decomposition of radiothorium, which, in turn, is a product of decomposition of thorium. Thorium x, though, as a rule, valueless in the treatment of cancer, owing doubtless to the rapidity with which it is itself decomposed, has been credited with marked efficiency in the treatment of gout, chronic rheumatism, and various blood disorders, particularly leukemia. Thus Plesch reported a case of myelogenous leukemia which had resisted x rays, in which a single injection of thorium x, administered intravenously in saline solution, sufficed to initiate recovery. Fifty-three days after the injection all the myelocytes had disappeared. In pernicious anemia he obtained good results where all other means had failed. In an almost moribund case, for instance, the red cells were brought up from 340,000 on the day of the injection to 2,270,000 thirteen days thereafter. Klemperer and Hirschfeld obtained equally good results in six out of nine cases of true leukemia, including cases in which x rays had totally failed. In pernicious anemia the results were not as favorable, only three out of seven cases having shown serious improvement. These authors emphasize the advisability of giving thorium x a trial in this disease, however, where arsenic and other classic measures have failed, and other conservative clinicians speak in the same vein.

Promising as this agent seems to be, its use is by no means free from danger as some writers seem to believe. Thorium x shows a strong predilection for the leucocytic apparatus. Domarus and Salle found experimentally that it inhibited leucocytosis and reduced the coagulation time of the blood. Arneth noted a similar action which he traced to the central leucocytogenic organs. This inhibition of leucocyte formation coexisting with continuous utilization and physiological disintegration of the white cells, the latter disappear. Although these effects were brought about by large doses, our lack of knowledge as to the size of the dose indicated in a given case and the likelihood that it varies to a certain extent with each case, probably account for the fact that toxic phenomena with extreme leucopenia and severe gastrointestinal disturbance have been observed in several cases, some of which ended fatally. Great care should, therefore, be the rule in using thorium x intravenously or subcutaneously until at least its physiological action and its dose will have been carefully studied by radiologists.

IMPORTANCE OF PURE DISTILLED WATER.

Wechselmann and Ehrlich, about two years ago, showed that some of the untoward effects of intravenous injections of salvarsan, such as fever, nausea, and vomiting, could with a very high degree of probability be attributed to protein derived from bacteria which were present in the distilled water employed in making the solutions. These observations directed attention to the inferior quality of the distilled water usually sold in pharmacies in Germany and Austria; Müller, for example, found that the bacterial counts of seventeen samples of such waters varied from 100,000 to 6,050,000 in a c.c. An intravenous injection of 300 c.c. of a salvarsan solution made with such water might thus contain one and one half billion bacteria. When it is recalled that water containing 300 bacteria in a c.c. is usually condemned for drinking purposes, it is evident that there is some justice in the comment made by a recent writer (Barladean, Pharmaceutische Centralkolle für Deutschland, 1913, p. 787) that some of the distilled water used in pharmaceutical work
approaches, in bacterial content, sewerage rather than bad drinking water. The use of freshly distilled water in preparing solutions of salvarsan seems to have materially reduced the number of cases in which unpleasant symptoms (fever and nausea) occur.

These observations have directed attention to the character of the water used in preparing solutions of other medicinal substances for intravenous or subcutaneous injections. Gazz, in a recent number of the Deutsche medizinische Wochenschrift, reports a case of sterile tissue destruction following the injection of novocaine; he attributed it to the (dead) bacteria contained in the water. Several recent writers (Samelson, Benidix, Bergmann, and Jörgensen) attribute the much discussed “salt fever” of infants (the fever which so often follows the subcutaneous injection of salt solution and which has been held to contraindicate saline infusions in infants) to the bacteria contained in the water employed in making the solution: the reaction did not occur if water free from dead bacteria was employed.

Attention is also being called to other possible sources of dangers in “distilled” water. Kohbrausch more than twenty years ago showed that even distilled water may abstract a considerable amount of alkaline material from glass; in some cases he found that as much as 0.5 gramme of such material was abstracted by a litre of water. Several recent writers (Matzenauer, Emery, Dreyfus) believe that this material may act injuriously on solutions of salvarsan just as it has been shown to be the chief cause of the decomposition (turning red) of solutions of eserine (Wolflin, Klinisches Monatsblatt für Augenheilkunde, 1913, p. 349).

The chills and fever which sometimes follow the intravenous injections of sterile solutions of lactose (for testing renal function) are attributed by Schlayer, to the protein derived from moulds and bacteria which grow on the lactose, unless special precautions are taken.

Thus the extension of the intravenous and hypodermic methods of administering drugs has brought out new facts, one of the most surprising of which is the effect of minute amounts of bacterial proteins. They show that simply distilling water and then boiling it again when it is to be used is not sufficient: the water should be preserved under aseptic conditions or, better, used soon after its preparation. For many purposes it is also desirable to use water which has not been allowed to remain too long in contact with glassware, especially of the cheaper grades which readily yield some of its constituents to water.

ESSENTIAL HEMATURIA AND ITS TREATMENT.

As hematuria is a symptom due to so many different causes which, though sometimes of but little moment, are often of the gravest character, it is a matter of the greatest importance in all cases, of course, where the source of the hemorrhage is not plainly evident, to endeavor to ascertain its source at the earliest possible moment. The sources of hematuria may be divided into three groups: Renal, including the pelvis of the kidney and the ureter; vesical, including the prostate; and urethral. Urethral hemorrhage though, strictly speaking, not hematuria, is for the sake of convenience always considered as such. Moreover, hematuria is a symptom which, as is well known, may also occur in certain morbid conditions of the blood, as in purpura, scurvy, smallpox, typhoid and malarial fevers, and likewise in some cases of metallic poisoning, as by mercury, lead, and arsenic.

Notwithstanding the improved diagnostic methods now at our disposal there is still found a certain proportion of instances of renal hematuria in which there is no clinical evidence of renal insufficiency, no visible organic change in the renal parenchyma, nor any evidence of renal infection. Dr. William F. Braasch, of Rochester, Minn., who, in a paper published in the Journal of the American Medical Association entitled Clinical Observations on Essential Hematuria, confines himself to the consideration of hematuria resulting from renal conditions, states that the operative records of the Mayo clinic up to June 1, 1913, show twenty-six cases of patients operated upon for hematuria for which no evident cause could be found, while the clinical records show fifty-one cases not operated on in which the clinical diagnosis of essential hematuria was evident. For lack of a more accurate term he retains that of “essential” for the type of hematuria referred to. The diagnosis of essential hematuria is most often confounded with that of chronic nephritis, infectious nephritis, pyelitis, neoplasm, tuberculosis, and lithiasis, and these are to be excluded through the failure to find the evidences characteristic of the various conditions present.

Of great interest is the aftercourse of cases of essential hematuria. Of the patients operated upon at the Mayo clinic, sixty-seven per cent. recovered after nephrectomy, which was performed in twelve of the cases, while of sixteen patients upon whom nephrectomy was done, fourteen recovered, one died, and one was lost sight of. Of the fifty-one patients not operated upon, it was possible to trace but forty-one. In twenty-six patients the affected kidney was merely catheterized, with cessation of
hematuria (which remained permanent in all but four) following. In eighteen the renal pelvis was overstretched with methylene blue or colloidal silver, with permanent cessation in all but three; while in six patients in which epinephrin, in solutions of one in two thousand, was introduced into the pelvis, recurring hematuria was reported in all except one, treated six months ago. From these results, Doctor Braasch very properly concludes that it would seem advisable, as a rule, to treat essential hematuria conservatively.

THE FUMIGATION OF VESSELS FOR THE DESTRUCTION OF RATS.

Among the very valuable reprints from the Public Health Reports, Number 132, that one entitled Fumigation of Vessels for the Destruction of Rats should be well considered by all physicians who are connected, in official capacities, with quarantine stations of ports. In the reprint, it is stated that the efficiency of sulphur fumigation rests on its well-demonstrated property of destroying vermin, its safety, and the ease with which it may be applied. For the destruction of rats on board of vessels as an antiplaque the burning of roll sulphur in iron pots has not been displaced by any of the more recently proposed methods. Hydrocyanic acid gas is rarely used on account of the danger to human life, while funnel gases require an expensive apparatus and are practical only for large spaces, such as the holds of vessels. But great stress must be laid upon the fact that such sulphur fumigation has to be done thoroughly and not in the routine method of burning a few sulphur pots in the vessel's hold, a procedure which is of little value and gives only a false sense of security. Every part of the vessel must be fumigated; the compartments must be clean, as empty as possible, and open. The fires must be drawn or banked; the main funnel grating over the engine room, and all other openings that cannot be tightly closed must be battened down. The dunnage must be piled and slung up, entirely free from the floor: planking boards, ropes, canvas, etc., have to be removed. In short, every hiding place for rats must be exposed to the fumes. Actual measurements of the cubic capacity of the vessel have to be considered, and the fumigation is to be done simultaneously in all compartments. Living quarters and engine rooms must receive seven hours exposure to 4.5 per cent. gas; while the hold is given an exposure of three per cent. gas for twelve hours or more. The vessel is to be anchored away from any dock. All parts of the vessel, including rafts, boats, lockers, bins, casings, furled sails, etc., have to be exposed to the fumigating gas. It has been found that it is best to use five pounds of sulphur to each one thousand cubic feet of space, which will produce 4.5 per cent. gas.

FRUIT DIET IN CARDIOVASCULAR AND RENAL DISORDERS.

According to the Paris médical of August 9, 1913, H. Surmont asserts that a fruit diet is indicated in all forms of arteriosclerosis, including those with aortic disease—with or without anginal pains—with pulmonary edema, with myocardial weakness, and with Bright's disease. Even in patients in whom the circulation is failing and who no longer respond to a milk diet and cardiotonic or diuretic drugs, the use of fruit may cause a surprising degree of improvement. The fruit to be employed may include all varieties available in the several seasons, and in most instances should be taken chiefly raw, with or without powdered sugar. The amount for an adult should be 1.5 kilograms of fresh fruits, together with 400 or 500 grammes of oily fruits such as almonds, walnuts, and hazelnuts, or preserved fruits such as prunes, raisins, dates, and figs. From three to five meals may be taken in a day. In patients already in a serious state, the fruit treatment should be preceded for one to three days by absolute rest in bed and the ingestion only of fifty grammes of water every half to one hour. After this the exclusive fruit diet should preferably be kept up for three to four weeks. In the obese and edematous, limitation to raw, fresh fruit may bring about a considerable decrease in weight, whereas in patients already reduced and weakened, special stress should be laid on the nuts and preserved fruits. When the patient tires of the diet, or the desired end has been attained, bread and butter should first be added, then a litre of milk and a couple of eggs, once and later twice a day. Such a combined diet can be continued for months without inconvenience. The fruit diet acts as a laxative, diuretic, and in particular, as an alkalizer and a source of mineral substances previously often lacking. It is also nontoxic, avoiding the harmful effects of retained nitrogenous wastes in the classes of cases referred to. Sterile grape juice may be given to patients unable to digest raw fruits and subject to constipation because of taking preserved and dry fruits alone.

PELLAGRA IN ENGLAND.

Gurth S. Blandy's attention was called to pellagra through reading the recent articles by Sambon, and he is able to add eleven cases to those already reported, his paper appearing in the Lancet of September 6, 1913. None of these cases are analyzed. All but one of the cases were in women; with one exception (aged seventy-four) all of the cases were in persons between the ages of twenty and forty years. The patients did not come from the lowest grades of society, and none was destitute nor suffering from privation. Some of the patients had lived so long in the asylum that that may be said to have
been the index of their social condition. The diet was liberal and contained little or no maize products. A striking feature of the series is the general severity of the cases. All of the patients were insane, and although it is said that pellagra may remain quiescent for years, Blandy finds "a great difficulty in believing that the insanity was not quite independent of any pellagrous factor." Except in one case the disease seems to have been contracted by the patients while in the asylum. Two cases occurred simultaneously, the patients being in contact with each other; a third was isolated by sex, but was in the same hospital block. Two cases seem to have developed after contact with a third at some previous time in the hospital. Another patient occupied a bed in the same ward that had previously housed two other patients. Though not wishing to express an opinion as to the mode of origin of the disease, Blandy says that it is easy to be carried away by Sambon's enthusiasm over his attractive theory of the spread of pellagra by the simulium. "While, however, it is comparatively easy to associate the life history of any individual patient in this country (England), when means of transit are so plentiful, with some or other river, it is almost impossible to find a case that can at no time have been in the near neighborhood of a simulium bearing stream."

Obituary.

REGINALD HEBER FITZ, M.D.,
of Boston.

Doctor Fitz died in Boston, on Tuesday, September 30, after an operation on the stomach. Born in Chelsea, Mass., on May 5, 1843, he received his education at Harvard, obtaining the degree of A. B. in 1864, of M. D. in 1868, and the honorary degree of LL. D. in 1895. He settled in Boston and in 1870 joined the teaching staff of his alma mater as instructor in pathological anatomy, becoming assistant professor of pathology in 1873 and full professor in 1878. From 1878 to 1892 he was Shattuck professor of pathology, and since 1892 Hersey professor of the theory and practice of physic. In 1908 he retired and was made an emeritus professor. Doctor Fitz was one of the leading men of Harvard University, and a well known practitioner of Boston. He contributed many essays to medical literature and is especially well known through his studies on appendicitis.

News Items.

A Joint Meeting of Pediatric Societies.—A joint meeting of the Philadelphia Pediatric Society, the New England Pediatric Society, the New Jersey Pediatric Society, and the Section in Pediatrics of the New York Academy of Medicine will be held in Boston on Saturday, November 8th.

Fifth District Medical Society.—At the seventh annual meeting of the Fifth District Branch of the Medical Society of the State of New York, held in Oneda on Thursday, October 24, the following officers were elected: President, Dr. Frederick H. Flaherty, of Syracuse; vice-president, Dr. W. D. Garlock, of Little Falls; secretary, Dr. J. F. McCall, of Watertown; treasurer, Dr. George F. Mills, of Oneida.

Professor Conklin to Give Gross Lecture.—At a meeting of the Philadelphia Pathological Society, to be held in Thomson Hall, College of Physicians, on the evening of October 24th, Dr. E. G. Conklin, professor of biology at Princeton University, will deliver the William D. Gross lecture, his subject being the Mechanism of Heredity and Development. All persons interested are invited to be present.

Clinical Lectures on Genitourinary and Venereal Diseases.—Beginning on November 3, 1913, and continuing for a period of four months, Dr. S. P. Conklin, of Philadelphia, will give a series of clinical lectures and demonstrations on genitourinary and venereal diseases, including the modern methods of diagnosis and treatment, every Monday evening at 8:30 o'clock, at the West Forty-second Street Dispensary, 328 West Forty-second Street, New York. The course will be free to physicians and advanced students in medicine.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Tuesday, October 14th. Pediatric Society; Wednesday, October 15th. Philadelphia County Medical Society (business meeting) and the Section in Otolaryngology of the College of Physicians; Thursday, October 16th, Northeast Branch of the Philadelphia County Medical Society and the Section in Ophthalmology of the College of Physicians; Thursday, October 17th, Southeast Branch of the Philadelphia County Medical Society.

Neurological Section of the Academy of Medicine.—The Section in Neurology and Psychiatry of the New York Academy of Medicine will meet on Tuesday evening, October 14th. The programme will include the following papers: Amnesia Due to Tobacco and Malaria, by Dr. S. P. Goodhart; What is a Complex? by Dr. H. W. Frink; Psychanalyis and Life, by Dr. Trigant Burrow; and a Terminal; Opportunities of the Psychotherapist, by Dr. James J. Putnam, of Boston. Dr. A. A. Brill and Dr. Louis Casamajor will take part in the discussion. Dr. E. W. Scripture is chairman of this section and Dr. I. Stetson is secretary.

Utah State Medical Association.—At the annual meeting of this association, held in Salt Lake City on Tuesday and Wednesday, September 23d and 24th, under the presidency of Dr. Andrew J. Homer, of Salt Lake City, the following officers were elected: President, Dr. John F. Critchlow, of Salt Lake City; first vice-president, Dr. Joseph R. Morrell, of Ogden; second vice-president, Dr. Heber E. Robinson, of American Fork; third vice-president, Dr. Margaret A. Freece, of Salina; secretary, Dr. William Brown Ewing, of Salt Lake City, reelected; treasurer, Dr. H. P. Kirtley, of Salt Lake City, reelected.

Action of Medical Congress in Regard to Syphilis.—At the joint session of the Sections in Forensic Medicine and Syphilology of the Seventeenth International Congress of Medicine, held in London on August 16, 1913, the following resolution was unanimously adopted.

That, sensible of the ravages wrought by syphilis in the health of the community, and deploiring the inadequacy of existing facilities for the checking of its dissemination, the International Medical Congress calls upon the governments of all the countries represented to institute a system of confidential notification of the disease to a sanitary authority, where such notification does not already exist, and to make systematic provision for the diagnosis and treatment of all cases of syphilis not otherwise provided for.

Postgraduate Instruction in the Medical Sciences.—In recent years there has been a growing desire among the physicians and surgeons of New York city for opportunities to keep abreast of the advancing knowledge of the medical sciences, particularly as such information bears upon the problems of clinical medicine. To meet this demand, the directors of some of the leading laboratories of New York have cooperated to offer postgraduate courses in their respective subjects. The institutions cooperating are: College of Physicians and Surgeons of Columbia University, New York University and Bellevue Hospital Medical College, Cornell University, College of Physicians and Surgeons of the Research Laboratory of the New York City Department of Health. Instruction will be by means of lectures, demonstrations, and laboratory work according to the manner of the subject to be presented. For information and details regarding the various courses, applicants are requested to communicate with the directors of the respective laboratories. For information as to facilities for study applications may be made to Haven Emerson, M. D., 120 East Sixty-second Street, New York.
Philadelphia Civil Service Examinations.—Among the positions for which the Philadelphia Civil Service Commission will hold examinations in the near future are the following in the Medical Service of the Department of Public Health and Charities: On October 23d, at 9:30 a. m., examinations for the positions of assistant physician (resident), with a salary of $600 to $900 a year, with room and board; assistant physician (resident), with salary $700 a year, with room and board; federal supervisor, with a salary of $700 a year, and school medical inspector (women), salary of $600 a year. On October 24th, at 9:30 a. m., an examination will be held for the position of dietician, with a salary of $720, and on October 25th, an examination for druggist, with a salary of $600 a year.

Surgeons of the Pennsylvania Railroad Hold Annual Meeting.—At the joint annual meeting of the Pennsylvania Railroad Surgeons' Association and the American Board of Surgery, held recently in Baltimore, Md., the following officers were elected: For lines east, Dr. George L. Roman, of Lambertville, president; Dr. Herbert F. Gillette, of Cuba, N. Y., first vice-president; Dr. William Martin, of Atlantic City, N. J., second vice-president; Dr. A. W. Coolcord, of Clairton, Pa., secretary; Dr. Joseph C. Egbert, of Wayne, treasurer. For lines west, Dr. H. P. Linsz, of Wheeling, W. Va., president; Dr. Hiran J. Conn, of Colfax, Ind., first vice-president; Dr. W. M. Johnson, second vice-president; Dr. J. D. McCann, of Monticello, Ind., secretary; Dr. O. E. Holloway, of Kensington, Ind., treasurer. Both associations voted to hold next year's meeting in Atlantic City, N. J.

Resolution of the Board of Directors Van Santvoord.—At a meeting of the board of trustees of Bellevue and Allied Hospitals, held on September 16th, the following resolutions on the death of Dr. Richard Van Santvoord were adopted:

Whereas, the trustees have learned with profound regret of the death of Dr. Richard Van Santvoord, for many years a member of the visiting staff of Harlem Hospital, and whereas they recognize the loss of one who gave always skillful and faithful service to the hospital and the patients entrusted to his care.

Resolved, That the trustees extend their sympathies to the family and friends of Dr. Van Santvoord in their great bereavement.

Resolved, That the trustees extend their sympathies to the family and friends of Dr. Van Santvoord in their great bereavement.

Resolved, That a copy of these resolutions be forwarded to his bereaved family.

J. K. Paulding, Secretary, Board of Trustees.

Personal.—Dr. Francis Winslow Palfrey has been appointed secretary to the faculty of Harvard Medical School, succeeding Dr. Channing Frothingham, who resigned. Dr. Willard Parker has been appointed secretary to the faculty of the graduate school of medicine of Harvard University.

Dr. Paul S. McKibben, of the University of Chicago, has been appointed professor of anatomy in the Western University, London, Ontario.

Dr. G. E. Coghil has been appointed associate professor of anatomy at the State University of Kansas, Lawrence.

Dr. Clara Moore, pathologist to the North Chicago Hospital, has been appointed instructor in clinical medicine and diagnosis at the University of Wisconsin.

Dr. Walter Mendelson, of New York, has been elected by the alumni of Columbia University to fill the vacancy in the board of trustees caused by the resignation of Mr. Herbert Smith.

First Convocation of the American College of Surgeons.—On the evening of November 13, 1913, will be held the first formal meeting for the conferring of fellowships on the members of the American College of Surgeons. Dr. Rickman Godlee, president of the Royal College of Surgeons of England, will deliver the principal address and extend, officially, greetings to our new organization. Dr. William Mayo, of Rochester, president of the College of Surgeons, Dr. J. M. T. Finney will deliver the presidential address, and formally confer the fellowships on all members of the organization who have qualified. Honorary fellowships will be conferred on a small number of foreign surgeons who have contributed to the science of surgery. In this way the College hopes to extend its recognition to those who have contributed so much to the advancement of the science and art of surgery. It is believed that the organization is the most complete and comprehensive representation of the surgical profession ever established.
Pith of Progressive Literature.

BERLINER KLINISCHE WOCHENSCHRIFT.

August 4, 1913.

Splenomegaly.—F. Kraus presents an extreme case of splenomegaly. The patient was poorly nourished, skin loose, mucous membranes pale, temperature elevated. A marked splenomegaly and hyperchronic anemia were present. Even in the standing posture the large spleen could be easily palpated. No parasites were found in the blood withdrawn from the spleen nor in the stools; the urine was normal. The pulse was somewhat hard, the tongue coated, and bowels constipated. The man was a Russian, sixty-two years of age; never had had any venereal infection. Wassermann reaction negative. No positive tuberculic reaction present. The patient believed he had been ill about three months; that his ailment began with headaches, muscular pains, digestive disturbances, drowsiness, etc. Gradually cardiac weakness developed; dyspepsia and anasarca ensued. Extirpation of the spleen was serious in the presence of myelosis. The only treatment left was the Röntgen ray, thorium X, and finally with benzol. Patient has been X-rayed since July 1st; six grammes of benzol in oil was given daily per rectum, and a salvarsan injection of 0.4 gramme followed once. On the whole the treatment had a favorable effect on the anemia.

The Source of Amniotic Fluid.—B. Wolff believes that liquor amnii is not produced by the mother; but by the living ovum. All late investigations have led to the knowledge of the close union of the fertilized ovum to the wall in which it implants itself. No blood is transferred, either directly or by filtration, to the fetal circulatory system. The amniotic fluid is produced by the activity of the fetal cells.

The Chemotherapeutic Treatment with Ethylhydrocuprin.—H. J. Vetlesen reports the treatment of nine patients, with fibrous pneumonia. The sole remedy used was ethylhydrocuprin, given in three daily doses of 0.5 gramme, especially during the febrile period was this treatment consistently used. Only occasionally were symptomatic remedies given. During convalescence the author gave bitter wine of iron after the ethylhydrocuprin had been discontinued. In reviewing the outcome of treatment with this remedy, it is striking with what promptness the disease took a favorable course. Defervescence ensued in forty-eight hours after the onset of the disease, in three cases. In two others after two days and one half. In two others in three days and one half. In one case in four days and finally, in one case in eight days. This last being a specially virulent, contagious form. A girl of five years and a boy of four years were taken down with the same disease in the home of the patient. The author emphasizes the necessity of early treatment.

Hemotology.—H. Strauss states his experience with patients suffering from chronic acholuric icterus with gout, and with chronic acholuric icterus without splenomegaly. This last is very rare—the one in question being the first which the author has seen without splenic tumor. The disease progresses with remissions and exacerbations. Whether the anemia is temporary or permanent is still questioned. Although a cure may be effected in a number of patients with hemolytic icterus, like some cases of Banti's disease, by extirpation of the spleen, such is not the case with all. Splenotoxic disintegration of albumin is not to be lightly considered. In a patient without splenomegaly, the blood changes were slight. The function of the liver was comparatively normal; the quantity of urobilin in the urine and feces was increased—but much more marked were those changes in the ailment when combined with gout. There were marked signs of anemia and bonymarrow irritation. The serum was rich in bilirubin. It must have contained an antihemolytic substance, at least, during the time of examination. The urine and feces contained specially large amounts of urobilin. The feces also contained great amounts of bilirubin. Under the influence of treatment, with benzol for forty-five days the leucocytes were decreased from 271,000 to 151,000. Two intravenous injections within thirty days, each of 3,000 E. S. E. thorium X the white blood corpuscles were reduced from 151,500 to 62,000. The splenic tumor was also greatly decreased. This proves thorium X to be an effectual remedy in leucemia, as well as in severe anemia. Many similar experiences have recently been added.

August 18, 1913.

The Beri Beri Question.—W. Caspari and M. Mosykowski present their contributions as follows: In 1911 Mosykowski reported practical experiences, while Caspari made a tour of investigation to New Guinea and as a result of the same concluded that beri beri, so called human neuritis, was a disease of disturbed metabolism, caused principally by food and irritating toxins. Other investigators also adhere to the infection theory. Mosykowski was able to bring about the disease, by a diet of polished rice, in Berlin. Here infection was out of the question. The authors hope, by their investigations, to prove that beri beri is toxic in its origin.

August 25, 1913.

Pathology of the Function of the Spleen.—H. Eppinger reports the following facts observed in clinical cases of splenomegaly. The removal of the spleen in Banti's symptom complex which had at first been viewed with some misgivings, now proves to be in higher favor. The brilliant results after removal of the spleen in hemolytic diseases are known. Then it is suggested that the spleen, not only has something to do with these pathological conditions, but that it may be the exclusive etiological factor of the disease. Excess and diminution of function are mostly produced by well characterized diseases. Icterus is a common symptom accompanying the diseases in which splenectomy is proposed. In most cases icterus disappears after the operation. When so called hypertrophic cirrhosis of the liver is seen to greatly improve after splenectomy, the disease is not so much to be sought in the liver, but rather outside of it. The
authors have tried to bring pernicious anemia and hemolytic icterus under simultaneous observation. In both instances an increased hemolytic was present. It may be assumed that with hematological icterus there is a concurrent regenerative power in the bone marrow; splenectomy is capable of checking marked hemolyticus, in hematological icterus, and the removal of the spleen is also beneficial in pernicious anemia. This, however, must not be considered the treatment in every case of pernicious anemia. Since this result is only attained by the removal of the spleen, it follows that the cause of the pernicious anemia must be sought in the spleen.

Electrotherapy for the Diminution of Abdominal Fat.—Carulla, of Barcelona, summarizes as follows: 1. By a simple technic, a reduction of sixty-six kilogrammes was obtained under a treatment, continued for nine months. 2. During the course of treatment, untoward secondary effects—dizziness, oppression, and nervous disturbances—were overcome by the high frequency current and Franklinization. 3. Before treatment there were present muscular contractions without pain, increase peripheral circulation, diaphoresis, acceleration of respiration, increased heart action; great amplitude of pulse and higher arterial tension. 4. As a result of treatment there occurred a retardation of the respiration and of the pulse rate and a lessening in tension of the bloodvessels. 5. Together with the marked decrease in weight, the patient experienced a sense of well being and energy. His sleeplessness disappeared, as well as the muscular pains, neuralgia, migraine, and dyspeptic symptoms. 6. The results attained attest the value of electrical treatment as an important therapeutic agent.

WIENER KLINISCHE WOCHENSCHRIFT.
August 7, 1913.

Vascular Reflexes.—L. Hess and E. von Bermann tested the reactions of the vessels in normal persons and also in others suffering from scleroderma, arteriosclerosis, and syringomyelia. The cases in which pathological conditions were present are given in detail. One interesting point brought out was that a vasodilatation followed irritation of the skin, even when there must be supposed to exist a complete interruption of the spinal reflex arch, and that consequently the reflex must take place through some other way.

Gonorrhea.—Brandweiter and Hoch say that autogenous gonococcus vaccines give quantitatively greater puncture reactions than allogenous monovalent or polyclonal vaccines in the same dose. The polyvalent causes a greater local reaction than the allogenous monovalent, and in this respect sometimes approaches closely the autogenous vaccine. Polyvalent vaccines of various origins, but analogous manufacture, give about the same reactions with the same dose. The superiority of the autogenous vaccine is also noticeable in the treatment of acute anterior urethritis.

A Case of Diphtheria Following Piercing of the Ears.—Richard Pollak reports a case in which a child had its ears pierced. More than three weeks later the punctures were covered with purulent scabs. Two days later a pustule appeared on the upper lip, then other pustules on the lips, gums, and tongue. Autopsy revealed a lobular pneumonia in the right upper lobe, degeneration of the cardiac muscle, liver, and kidneys, and the bacteriological examination revealed the presence of diphtheria bacilli.

August 14, 1913.

The Vagotonic Pupillary Phenomenon.—Rudolf Somogyi says that Koranyi had observed that in those patients in whom other conditions indicated an increase of the tonic of the vagus deep inspiration caused a dilatation of the pupil, followed by a contraction during expiration. He has now studied this phenomenon in 120 patients, forty-two of whom were between thirteen and twenty-five years old, seventy-eight between twenty-five and sixty-seven. In the first group thirty-four had respiratory arrhythmia of the heart, fourteen the respiratory phenomenon of the pupils. In the second group thirty-nine had respiratory cardiac arrhythmia, six the respiratory pupillary phenomenon, showing that the latter is more common in young people. He thinks it most probable that the same causes act as in respiratory arrhythmia.

Irrigation with Ether in Perforation Peritonitis.—Franz Dergane reports two cases in which peritonitis was caused by a perforating ulcer of the stomach, or a rupture of the intestine. Laparotomy was performed in each case, revealing an early stage of an extensive peritonitis. The abdominal cavity was washed out with hot, sterile saline, dried with cotton, and then flushed with ether, which was immediately wiped out with cotton. Both patients made an excellent recovery. He calls attention to the exciting noise made by the ether when it was poured into the cavity.

Acute Polyarthritis in the Late Stage of Syphilis.—W. Huzar says that there are forms of acute multiple arthritis due to syphilis in its late stage which bear a perfect, or almost perfect resemblance to acute articular rheumatism, of which he gives three examples. Suppuration does not take place in these cases. For this reason one should think of syphilis and search for its symptoms, and when these cannot be found, try an antisyphilitic treatment in all cases of febrile inflammation of the joints which exhibit a marked resistance to the usual treatment. Mixed treatment is advised, and when this is without effect, salvarsan.

August 21, 1913.

Reinfection with Syphilis within Three and a Half Months.—Moriz Bächl reports a case in which a man appeared on February 18, 1913, with a chancro on his glans penis. Wassermann's reaction was negative. Four doses of neosalvarsan were injected intravenously in the course of the next month. On June 4th he reappeared with another chancro in the coronal sulcus. Wassermann's reaction was negative at first, but became positive on the 11th. The exanthem appeared in due time. The first chancro was proved to be such by its clinical appearance, and by bacteriological investigation. The second chancro contained spirochaete, and the syphilis took its usual course in spite of the treatment with neosalvarsan to which the patient had been subjected.
Acute Necrosis of the Pancreas.—Josef Gobiet concludes from his observations that the pancreas ferment theory gives the most natural explanation of the peculiar clinical picture, in which symptoms of poisoning are most prominent, that leads rapidly to death in the worst cases, and takes a more benign course in others, according to the amount of the pancreas poison produced and absorbed. Consequently the prognosis depends on the quantity of toxine produced, which in turn depends on the local extent of the process in the gland. This is in agreement with the clinical experience that the cases of total necrosis rapidly prove fatal, and that the clinical picture and the findings on autopsy perfectly simulate those of a poisoning. In some cases the diagnosis can be made with certainty, in others with great probability, before operation. The diagnosis in the early stage is based on the symptoms of poisoning, associated with great shock, the peculiar epigastric pains, which may be differentiated from those of gallstones, and the history. When the diagnosis is uncertain and the question of operation is doubtful, aid may be obtained from an isolated inflation of the transverse colon, which is very often demonstrable in the early stage and points to the pancreas as the focus of disease. The only rational treatment is to lay the pancreas bare at the earliest possible moment, to incise it and insert a tampon.

CENTRALBLATT FÜR ALLGEMEINE PATHOLOGIE UND PATHOLOGISCHE ANATOMIE.

Experimental Investigation in Cancer.—Novell makes some very interesting claims concerning the experimental production of cancer. He obtains from recently removed cancers, presumably human, although the author does not so state, an extract in the form of crystals. A sterile solution of this is made and injected into rabbits. The author summarizes his work as follows: That a highly poisonous substance, free from bacteria, may be obtained from cancer. That this material is characteristic of cancer and when injected into rabbits will cause the growth of cancer. Such tumors are followed by the formation of secondary growths with the development of cachexia. The repeated injections of sublethal doses have been found to confer immunity upon the rabbits.

PARIS MÉDICAL.

Treatment of Movable Kidney.—F. Cathelin disapproves of the Hahn-Anyon method of introducing catgut sutures for the purpose of fixing a movable kidney, chiefly on the ground that the transverse direction in which the six strands of gut are tied, after being passed through the renal parenchyma, tends to "strangle" the portion of the kidney included in them. Instead he uses only two strands, which are passed through the kidney obliquely and almost at right angles. The extremities of each of these strands are, respectively, tied horizontally across the kidney with the extremities of the other strand lying opposite as they emerge from the kidney substance, a triple knot being made in each case. The ends hanging from the upper knot are then tied around the twelfth rib if it be sufficiently long—otherwise around the costotransverse ligament of Henle—and the ends from the lower knot in a broad loop to the anterior and posterior musculofascial layers. An added advantage of this procedure is that the lower pole of the kidney is held in a relatively lateral position, corresponding with its normal condition and giving ample room for the ureter. Good operative results followed the employment of this mode of fixation in the three cases in which it has so far been tried.

PRESSE MÉDICALE.

Relationship of Appendicitis to Inflammation of Meckel's Diverticulum.—M. Guibé believes simultaneous disease of the appendix and Meckel's diverticulum to occur rather frequently. Either the two affections merely coincide, no causal relationship existing between them, or the one is secondary to the other. In the latter event, appendicitis is doubtless usually the primary condition, the infection of the diverticulum later giving rise, however, to a disturbance in it so marked as to overshadow the appendicular condition. The author cites cases illustrating each possible condition referred to, and in particular, reports a personal case in which, three and a half months after an operation for gangrenous appendicitis, he intervened again because of further abdominal discomfort and in order to remedy a protrusion at the site of the previous incision. The free tip of a Meckel's diverticulum was found firmly adherent to the cecum. Upon removal of the diverticulum, it proved to be the seat of a chronic inflammatory process extending inward from the serous into the subserous layer, but practically stopping at the muscularis.

Fibroma of the Cecum.—J. L. Faure and B. Desplas report a case of pure cecal fibroma in a woman twenty-four years of age, and review the literature of benign tumors of the intestine. The growth in their case was of the size of a child's head, and was diagnosed at first as a uterine fibroma, as it was dependent in the pelvis and was freely movable. The right iliac fossa was free, but the patient, had presented symptoms which might with propriety have been regarded as secondary to a chronic appendicitis. The tumor was removed by section of the ileum ten centimetres from the ileocecal valve and of the ascending colon two finger-breadths above the tumor, the open ends of gut being closed and a laterolateral anastomosis established. Recovery followed.

SEMAINE MÉDICALE.

Duodenal Ulcer in Children.—L. Cheinisse calls attention to the fact that, according to recent statistics, duodenal ulcer occurs more frequently in the first year of life than at any other age. In spite of the difficulty generally attending the diagnosis of duodenal ulcer, it is not impossible to recognize the affection even in young children. The chief basis of such a diagnosis is, indeed, the appearance of intestinal hemorrhage or peritonitis, either of which
threatens the life of the little patient. Duodenal ulcer may, however, terminate in spontaneous recovery, or even be entirely overlooked. Von Torday and others have pointed out that the clinical phenomena of pyloric stenosis may sometimes be produced by duodenal ulcer. As for treatment, subcutaneous injections of gelatin have appeared in a few cases to act favorably on the hemorrhage. Breast-feeding should, according to Helmholz, alone be recommended, and the amount of milk taken at each feeding restricted at first to ninety or one hundred grammes for each kilogramme of body weight. Where perforation occurs, early laparotomy and suture of the ulcer is indicated. Pichat's case proved that such intervention may save life even twenty-four hours after the initial symptoms. Although the two youngest patients so far operated upon and cured were fourteen and fifteen and a half years, respectively, operation would seem to be indicated even in infants. In fact, according to Kuttner, it should be resorted to whenever, the diagnosis of duodenal ulcer being assured, the usual therapeutic measures fail or hemorrhage sufficient seriously to affect the patient's general condition takes place.

**Bilateral Ligation of the External Carotid in Facial Surgery.**—H. Vulliet recommends ligation of both external carotids instead of ligation of only that on the operated side, in extensive operations in the facial region, e.g., in removal of the superior maxilla. In a considerable number of cases unilateral ligation does not prevent hemorrhage sufficiently for ideal operative purposes, the operator feeling hurried and perhaps not dissecting carefully enough in the removal of malignant growths. The bleeding is accounted for by anastomoses of the two external carotids in the labial region. Ligation of both these vessels is known to be devoid of danger, and was found completely effective by the author in preventing hemorrhage.

*September 20, 1893.*

**Suggestions for the Technic of a New Method of Performing Wertheim's Abdominal Panhysterectomy.**—According to Charles P. Childe, Wertheim's operation is associated with two conspicuous dangers—shock, because of the unfavorable conditions of the patient's general health, and sepsis, because in addition to circumstances favorable to sepsis being present, a septic stage is introduced of necessity into the operation itself. He gives the special conditions favoring infection as: 1. The fact of the patient's being in a reduced state of health with diminished resistance. 2. Three extensive wounds are exposed to infection—the peritoneum, the abdominal incision, and the pelvic tissues. 3. The fact that the pelvic wound is open to the exterior through the vagina. 4. The free opening of the space of Retzius. To obviate these dangers, Childe, after the patient is anesthetized and placed in the lithotomy position, removes all of the soft growth with scissors and sharp spoon and thoroughly applies the Paquelin cautery to the raw area. The vagina is then dried thoroughly and painted with a two per cent. solution of iodine in alcohol and is closely packed with dry sterile gauze. When about to divide the vagina in the course of the operation, the gauze is to be withdrawn by an assistant who is not taking part in the operation. During the operation the area about the uterus is completely surrounded by two large gauze packs wrung out of salt solution and introduced just prior to the division of the vagina. Immediately after this division these gauze packs are folded up, enclosing the uterus while it is removed from the abdomen. It is essential to secure perfect hemostasis, and this should be done with the use of the least amount of suture material possible. By means of strong crushing forceps, modeled in much the shape of Wertheim's vaginal forceps, Childe secures perfect hemostasis with the use of but four ligatures—one for each of the uterine and ovarian arteries. Drainage is not necessary in cases in which hemostasis is good.

**A Case of Carcinoma of the Pelvic Colon, Ovarian Tumor, and Appendicitis.**—Lawrie McGavin's patient was a married woman thirty-eight years of age, who in September, 1908, had her left ovary and tube removed because they were giving pain, owing to their adhesion to a mass in the lower part of the pelvic colon. After recovery from this operation she came under the care of the author, who operated and removed the whole sigmoid with its mesocolon, making an artificial anus. The removed sigmoid contained a ring carcinoma of the columnar cell type. No glandular enlargement was noticed. A year later an acute appendicitis developed, for which she underwent a third laparotomy with excellent recovery. In a short while it became necessary to cautery a vesical nevus. Eighteen months later pain developed in the right side of the abdomen, and upon operation the right tube and ovary were removed on account of a benign fibroadenoma. At the time of this operation McGavin implanted the rectum, by this time much narrowed, into the lower portion of the transverse colon, and closed her colostomy wound. The closure of this was not complete, and, after a period, during which her bowels moved through the rectum, she began to have pain and difficulty with such attempted movements, which soon began to escape from the old colostomy opening. After due consideration it was determined to attempt an enlargement of the narrowed rectum where it led off from the colon. This was accomplished successfully by means of a longitudinal incision which was closed transversely, as in pyloroplasty. A complete recovery ensued, with closure of the colostomy and perfect control and function of the restored rectum. After a period of over four and a half years there has been no recurrence of the malignant growth.

**True Total Enucleation of Two Hydatid Cysts from the Same Liver.**—J. B. Buckley succeeded in dissecting out two cysts, one larger the other smaller than a tennis ball, from the liver of a young girl without injuring the organ or inducing any material hemorrhage. The entire cyst wall was removed, leaving what appeared to be normal liver tissue. Recovery was complete and rapid.

**A Method of Operating for Radical Cure of Inguinal Hernia.**—William T. F. Davies begins his incision just internal to and above the pubic spine and runs it parallel with the fibres of the
aponeurosis of the external oblique, from which the skin and subcutaneous tissues are raised. After defining the pillars of the ring, the external oblique is split far enough to give room. The lower margin of the internal oblique is exposed and retracted upward and the peritoneum (not the sac) is incised from the internal ring upward. The neck of the sac can now be seen from the inside, and the contained structures are withdrawn from it. The peritoneal incision is now extended down to and is carried around the neck of the sac, cutting it off as a glove finger might be cut from a glove. The abdominal peritoneum is next closed with a continuous suture and attention is turned to the sac, which is completely removed.

**Rhinocleroma.**—Owen Richards calls attention to the utter impossibility of curing this deforming disease by surgical or medical measures and reports the use of a vaccine prepared from the bacillus which is constantly found in the deeper tissues of the diseased region. He used the vaccine in four cases, giving doses up to twenty thousand million organisms, without producing the least effect, either harmful or beneficial. He concludes that such treatment is useless.

**LANCET.**

**September 20, 1933.**

**The Dynamic Side of Biochemistry.**—F. Gowland Hopkins says that it is a striking fact that all the known complexes of the cells—the proteins, the nucleic acids, the phosphorous compounds, etc.—are susceptible of hydrolysis by catalytic agents. These catalytic agents, he believes, are always present or potentially so. An honest appraisal of the experimental evidence shows that it points to the conclusion that the complexes are unstable to hydrolytic processes only. While intact and under normal conditions of the body, they are resistant to other types of change, while their hydrolytic products are much more stable. Inasmuch as hydrolytic agents are present in the cell, we must suppose that at any moment there is equilibrium between these complexes and their watersoluble hydrolytic products, though the amount of the latter present at any moment may be very small. Hopkins regards assimilation and dissimilisation when very strictly defined, as being dependent upon changes in this equilibrium alone. They are processes of condensation and hydrolysis respectively. Substances foreign to the normal constitution of the complexes—including both extraneous substances and material for assimilation but not yet ready for condensation, or metabolites which are no longer simple hydrolytic products—never enter nor reenter the complexes. They may undergo changes within the cell, but not as a part of the complexes. The normality of the cell proteins seems to be maintained by processes which precede actual condensation or assimilation. And conversely, when the cell balance leans toward dissimilisation the amino acids which are liberated by hydrolysis undergo further change outside the complexes themselves. The equilibrium of the whole system must, to a greater or less extent, be affected by a change in any one phase. "A happening of any kind in the fluid phases must affect the chemical equilibrium and, no less, the physicochemical equilibrium, between them and the complexes or less fluid phases. A drug may have an action on a cell, even though it remain in solution, and it may have a specific action because its molecular constitution leads it to intrude into, and modify the course of, some one, rather than any other of the numerous simple chemical reactions proceeding in the cells of different tissues." Each chemical reaction within the cell is controlled by a specific catalyst. These catalytic agents are what are known as enzymes. When we consider the great multiplicity of the reactions which take place in the animal body, this view of an individual catalytic agent for each process calls for a myriad of such agents. But recent work by Abderhalden and others seem to confirm the conception of the need for such a multitude of specific catalytic agents, and to give us ground for the belief in their actual presence. It has also been shown to be possible for the cell to acquire new catalytic agents upon the necessity for them arising. Such newly acquired agents, or the ability to form them, is transmitted throughout the descendants of such a cell. Hopkins's theory of the existence of this myriad of catalytic agents calls for an extreme complexity of process, but, he says, "Underlying the extreme complexity we may discover a simplicity which now escapes us."

**The Detection of Small Amounts of Glucose in Urine.**—Sydney W. Cole gives the fallacies of Fehling's test as: 1. Urates reduce the solution, as does also creatinine. 2. An excess of sodium hydroxide destroys a small amount of glucose. 3. Conjugate glycuronates are hydrolysed to reducing substances by sodium hydroxide. 4. The mixed solution is unstable. 5. The solution is reduced by lactose and by pentoses. In a large number of urines as much as 0.5 per cent. of glucose can be added without the urine's giving a typical reduction with Fehling's solution. Cole gives his new method as follows:

In a dry boiling tube, or large test tube, place about 1 gramme of Merck's pure blood charcoal. Add 10 c.c. of the urine and shake from side to side thorough-ly. Heat to boiling point, shaking the whole time. Cool thoroughly under the tap and shake at intervals for about five minutes. Filter through a small paper (9 to 11 cm. in diameter) into a rather wide test tube containing about 0.5 gramme of anhydrous sodium carbonate. When the fluid has filtered through add 6 drops of pure glycricin, shake and heat to boiling. Note the time when boiling commences. Maintain active boiling for 50 seconds, shaking from side to side to prevent spurtting. Immediately add 1 drops of a 5 per cent. solution of crystallized copper sulphate. Shake for a moment to mix the solution, and allow the tube to stand without further heating for one minute. With normal urine the fluid remains blue, with a variable amount of grayish precipitate of the earthy phosphates. If glucose is present to the extent of 0.02 per cent. or more above the average normal amount of blue color is discharged, and a yellowish precipitate of cuprous hydroxide forms.

The two fundamental principles underlying this method are: 1. Charcoal absorbs the greater part of nonsaccharine reducing substances of normal urine, the greater part of any lactose present, and also a certain amount of the glucose present. 2. The filtrate is boiled with sodium carbonate, and thus converted into a reducing substance which reacts with the copper subsequently added. It is to
be noted that normal urine contains about 0.03 to 0.08 per cent. of glucose. The author also gives a method for the identification of lactose in the urine, which consists in boiling the urine with charcoal, cooling, and filtering. The residue is then extracted with water and glacial acetic acid, boiled, and filtered into a tube containing phenylhydrazine hydrochloride. A lactosazone is thus formed and identified by its crystalline form.

BOSTON MEDICAL AND SURGICAL JOURNAL.
September 25, 1913.

Needs of the Future in Hospital Administration.—Frederic A. Washburn urges that the great professional departments of a large modern hospital should each have a single head with a service uninterrupted, except for the necessary vacation, on a salary. These heads to form a committee of not more than five or six to meet with the superintendent and consider the problems of medical and surgical administration, and the great questions of the medical and surgical policy of the institution, so as to obtain an efficient organization. The standard of efficiency of an entirely unpaid medical staff has in many instances been high, but it does not meet the requirements of the present day. The superintendent with this committee should see that the men appointed on the staff are the very best possible, and that they work for the greatest efficiency of the hospital, rather than for their personal aggrandizement. The committee could also inspect and criticize the work of the various departments, so as to prevent slipshod work. More thought should be given to the needs of the community when a small general hospital is to be erected. Often it could be erected at a central point which would serve several towns and be able to command better work than could several smaller institutions in the various towns. There is a tendency in some of the smaller hospitals for members of the staff to attempt surgery for which they have had no adequate training. The proposal to license surgeons has been made, but a public sentiment must be developed which will make ignorant surgery impossible. A surgeon of small experience must learn that it is no disgrace to admit that a given patient's chances are better in the hands of another man. No hospital with low standards of deportment and decorum can ever permanently flourish or do good work, and the question is raised whether this has anything to do with the difficulty some hospitals have in getting nurses. Too many small hospitals are started without adequate provision for their support. The result is a constant struggle and a burdening of the unfortunate nurse in charge. No hospital should be started until it has been clearly shown to be necessary that the location suggested best meets the need, that there is adequate support in evidence, and that its conduct is in the hands of those whose ideals are high and whose methods are practical.

Atrophic Rhinitis with Ozema. Its Etiology and Surgical Treatment.—Francis P. Emerson believes sinus disease to be the cause of atrophic rhinitis, and says that he has never seen a case that was not relieved by thorough drainage, instead of being made worse, as would be the case if trauma and increased air space were added to a genuine atrophic mucosa. The crust formation and fetor when unilaterally are always on the wide side, where they have apparently been preceded by a compensatory hypertrophy of the second turbinate, which in turn interferes with the proper drainage of a subsequent sinus infection. The discharge of pus over a mucous surface causes the mucous membrane to appear glazed, dry, and to have an exudate, but that this is not a true atrophy is shown by the return of function after free drainage and the cure of the focal infection. Radical surgery to establish free drainage lessens the tendency to crustformation, instead of increasing it. Ethmoid disease, the writer believes, is the most constant of the infectious processes in the nasal chambers, and his cases have shown the morbid process more uniformly in these and the sphenoid sinuses. Next in frequency have been the ethmoid, sphenoid, and frontal, last the ethmoid, sphenoid, and antrum.

Ozone; Its Bactericidal, Physiological, and Deodorizing Action.—From their experimental investigation of this subject, and in view of the evidence already in existence, E. O. Jordan and A. J. Carlson conclude that the hygienic value of ozone in room ventilation would be hardly worth considering were it not for the persistent and sometimes extravagant claims made by the manufacturers and promoters of ozone generators. So far as the destruction of bacteria is concerned, these statements have little or no foundation, and there is no evidence for supposing that a quantity of ozone which can be tolerated by man has the least germicidal action. Disinfection in a closed room without inmates can be much more effectively carried out by means of formaldehyde or other gaseous disinfectant, and therefore ozone has no place in practical room disinfection.

Isolation of the Typhoid Bacillus from Milk Which Caused a Typhoid Outbreak.—The outbreak referred to occurred in a suburban town in Maryland, and W. R. Stokes and H. W. Stoner, who made the laboratory investigation, point out that the first point of interest in their study consists in the isolation of a typical typhoid bacillus from the milk. and that the study is also of interest as demonstrating the relation of infected milk to the epidemiology of typhoid and containing the methods by which the cause of the outbreak was recognized and by which its further spread was avert.

The Effects of Colloidal Copper, with an Analysis of the Therapeutic Criteria in Human Cancer.—Richard Weil asserts that the demonstrable reduction in size of a tumor, of a kind not to be attributed to the natural processes of evolution of that tumor or of its associated lesions, is the one essential feature of effective therapeutic intervention. He reports twelve cases of malignant disease in which the preparation described by Loeb as colloidal copper was administered, in eight of which the treatment was thoroughly carried out. In most of the cases the treatment resulted in the production of mild constitutional effects, such as fever, chills, nausea, some loss in weight, slight reduction of hemoglobin, and occasional albuminuria or hemoglobinuria. Chemical analysis of two tumors from treated patients failed to reveal the presence of copper, while in a liver obtained at necropsy it was present in appreciable quantity. Judged by certain clinical criteria which were adopted as a reliable standard of therapeutic effectiveness, the treatment has not appeared to exert a destructive action on the tumor tissue in any instance.

MEDICAL RECORD.
September 27, 1913.

A Contribution to the Study of Chronic Intestinal Stasis.—W. S. Bainbridge says that while the existence of chronic intestinal stasis has long been known as a possible contingency, it was left to Lane, of London, to establish the fact that many of the factors concerned in the production of its various types are associated with, or perhaps dependent upon, an already existent chronic intestinal stasis, and that they are, in reality, end results of such a condition. Having given an outline of Lane’s work in this connection, and having considered the cases of intestinal stasis with reference to the point of kinking and to the dominant features in the symptom complex, he takes up the classification of cases with reference to treatment; describing the following types: 1. Atonic or asthenic, in which there is a general loss of muscular tone and nervous energy, with a slight degree of ptosis of the hollow viscer. In the treatment of this class of cases liquid paraffin has been found particularly useful. 2. Misplaced appendix. 3. Ileal kink, from evoluntary bands—called by Lane “crystallization of lines of strain.” The milder degrees may be corrected by simply cutting the adhesive bands; taking care to cut one way and sew up another in such a way as to lengthen. In the form with broad bands, however, it may be necessary to divide the ileum, inserting it directly into the pelvic colon or rectum obliquely by an end to end anastomosis. 4. Kinking of duodenoejunal junction, usually secondary to ileal stasis. This kink may be corrected by cutting one way and sewing the other, or the loop of jejunum may be placed in the position of gastroenterostomy, held by several stitches of silk or linen. In some of the cases it may be necessary to resort to ileocolostomy. 5. Changes at the hepatic and splenic flexures of the colon, often with the formation of adhesions. In mild cases, with prolapse of the colon, Coffey’s omentopexy may be employed. In the presence of more marked adhesions, with disease of the transverse colon, the question of colectomy may be considered; though other attempts at correction should be made before this radical procedure is resorted to. 6. Changes at the sigmoid loop. In some of these cases the portion of mobile gut which intervenes between the upper fixed portion of the loop and the portion of the
rectum without peritoneal covering is exceedingly long, and this renders it possible to insert the ileum into the mobile loop, close to its termination. Anastomosis should be between the ileum and the beginning of the pelvic lesion. 7. extreme cases, with diverticulum. Exection of the large bowel is indicated. 8. Various kinds of adhesions of an inflammatory and noninflammatory nature. The adhesions should be removed, and the raw surfaces covered. The author next describes the preparation of the patient for operation and the technic of the two operations advocated by Lane, ileocolostomy (Lane's "shorthcircuiting" operation) and coclectomy. He then considers the prognosis, and, in conclusion, says that in the vast majority of instances, unless there is a congenital defect, the conditions described are preventable, and should not be allowed to progress to the degree which calls for operative interference. With a more intelligent understanding of the importance of exercise, of proper hygienic régime, of position, and of adequate support of the abdominal organs, chronic intestinal stasis will be forestalled.

Exophthalmic Goitre Cured by Ligating One Superior Thyroid Artery.—L. F. Watson finds that the simple and conservative operations are steadily gaining favor in the treatment of goitre because of their safety and ease of application. A single or double ligation always benefits, even though it does not cure every case. Operations on the thyroid, he says, should be performed under local anesthesia whenever possible. Ligation should be preceded by several days' rest in bed while the operator gains the patient's confidence. One hour before operation the patient receives a dose of morphine or morphia and hyoscine, sufficient to allay restlessness and prevent psychic shock.

A Collapsible Weighted Stomach Tube and a New Gastric Glass Bulb.—These are presented by I. O. Palefski. The stomach tube has a gold plated lead tip, the upper half of which is hollow and perforated and the distal half solid, while the tubing is soft and collapsible, and is marked off at fifteen and at forty-five centimetres from the metallic tip, to show when the latter has reached beyond the pharynx and cardia respectively. When the patient refuses to swallow the tip a flexible stylet is employed. The following are the advantages claimed for the Palefski tube: 1. Its tubing has no resistance; hence it does not irritate the gastric mucosa. Blood present in the stomach contents will therefore point to some organic condition. 2. By its use a moderate degree of gastric stenosis will be readily detected. 3. It may be kept in the stomach as long as desired. 4. It lessens preparation and renders assistance unnecessary in lavage and the extraction of test meals. 5. As its introduction causes no sensation, it may be employed in conditions in which the use of the ordinary stomach tube is contraindicated. 6. Following lavage or extraction of test meals, an inflating bulb attached to the outer end of the tube will inflate the stomach to any desirable degree without any distress whatsoever. 7. It enables one to study the functions and disturbances of the stomach more readily and accurately. The purpose of the glass bulb is to facilitate the aspiration and collections of gastric contents, and it is attached to the outer end of the stomach tube after its introduction, when a suction bulb is employed, to aspirate the gastric contents into it. It is a graduated ten ounce glass bulb having two inlets and two outlets, for air and gastric contents respectively, each opened or closed with stopcocks.

AMERICAN JOURNAL OF SURGERY.
August, 1913.

Tendon Transplantation in Talipes from Anterior Poliomyelitis.—B. F. Zimmerman successfully employs the following technic which he says is comparatively simple and easy of accomplishment: 1. An incision is made along the inner anterior aspect of the foot from the first metatarsal bone upward to the annular ligament of the ankle. 2. The tendon of the tibialis anticus is isolated and a portion (at least one half) detached at the point of attachment, carrying therewith the peristeum and a thin section of bone. 3. The tendon is split upward to the annular ligament, and then beneath the annular ligament and above as far as the attachment to the muscle if deemed advisable. 4. A counter opening is then made on the outer side of the foot over the calcaneocuboid articulation and a pair of hemostatic forceps or blunt scissors being passed beneath the skin and superficial to the extensor tendons, the tendon is grasped and "dragged" through this tunnel and out at the counter incision. 5. The calcaneocuboid joint is then opened and a narrow strip of the articular surface on either side removed, the joint being closed with catgut sutures. 6. The periosteum is then incised and elevated, and the detached tendon with its periosteum and bone placed beneath the elevated periosteum of the cuboid or os calcis, being held in position by a fine silk suture passed through the reflected periosteum and the tendon. 7. The periosteum is then sutured and the wound closed with catgut, a plaster cast being applied to maintain the foot in an overcorrected position. The writer insists that care should always be exercised not to have too much or too little tension upon the transplanted tendon. The tendon should be on slight tension, however, when the foot is in a slightly overcorrected position.

The Treatment of the Pathological Lingual Tonsil.—Harold Hayes says that the simplest way to remove the lingual tonsil is by means of the Myles lingual tonsillectome. The base of the tongue and surrounding parts must first be thoroughly coagulated, and then, after the patient is told how to properly hold out his tongue, one should have the parts under direct inspection with a laryngeal mirror. Operative work is best done when the operator stands over the patient. The tonsillectome is brought over the growth, and as soon as it is in position the mirror is withdrawn and pressure is made firmly with the fingers of the other hand at the tip of the instrument. If this is not done, the cutting part of the instrument will invariably slip from and over the growth and nothing will be removed. Considerable bleeding attends the operation and often this will not stop sufficiently for one to get another inspection of the throat in order to see if any of the mass still remains. As the hyper trophy is bilo-
bar, it is absolutely necessary in many cases to insert the instrument a second time and under no circumstances should this be done unless one can see every part. If bleeding is too profuse to be stopped at one sitting, it is far better to finish the operation another time. The aftertreatment of this operation needs very little comment.

Proceedings of Societies.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-Sixth Annual Meeting, held at Providence, R. I., September 16, 17, and 18, 1913.

The President, Dr. Miles F. Porter, of Fort Wayne, Indiana, in the Chair.

(Concluded from page 693.)

Conservatism in Operations for Acute Infectious Pelvic Disease.—Dr. Budd Van Sweringen, of Fort Wayne, said that one should not allow a large pelvic exudate or a tubo-ovarian abscess to remain until absorbed, as it meant chronic invalidism. Pur should be evacuated as soon as it was safe to do so. But when once inside the abdomen for this purpose, it was wrong to think that all pathology present must be removed with the knife. Ample provision for drainage and the ablation of the original focus would be sufficient and would save many a tube and ovary which would result in much greater peace and happiness to the patient. Illustrative cases were reported.

The Significance of Hematuria and Its Management.—Dr. J. Garland Sherrill, of Louisville, stated that according to its causation, hematuria was classified as: 1. Traumatic, including accidental injury and also the minor traumatism resulting from stones. 2. Infectious, including acute nephritis, chronic infectious affections of the kidney, tuberculosis, acute and chronic inflammation of the pelvis of the kidney, ureter, bladder, prostate, and also of the urethra. 3. Vascular, blood dyscrasia, such as hemophilia, e., venous obstruction of the kidney; varicosity of the vesical veins, especially that due to prostatic engorgement. 4. Chemical, in which class should be placed hemorrhages from irritating drugs, as turpentine, cantharides, etc. 5. Toxie, in which the hemorrhage was the result of vascular changes occurring in severe toxemias, such as those resulting from malaria, acute yellow atrophy of the liver, yellow fever, seury, etc. 6. Neoplastic. 7. Parasitic. Renal hematuria was probably the form most interesting to the surgeon. Laceration of the kidney, gunshot and stab wounds, frequently caused hemorrhage which appeared in the urine. Tuberculosis of the kidney presented in hematuria as an early symptom, the amount of blood varying very greatly in different cases. In the treatment of hematuria, rest was of the greatest importance, and he advised the use of turpentine in small doses. Calculus, tumors, major traumatism, and unilateral tuberculosis would demand operative intervention.

Acute Unilateral Hematogenous Nephritis.—

Dr. Curtis S. Foster, of Pittsburgh, stated that in the acute cases, with multiple miliary abscesses, and from which an overwhelming toxemia resulted, nephrectomy must be the operation of choice if we would save the patient's life. Of the fourteen cases of this type encountered by Brewer, two were untreated, and in four nephrotomy with drainage was done. These patients all died. The remaining eight were treated by nephrectomy with recovery in each case. In the acute diffuse inflammation of the kidney, the treatment was not so well defined and must depend more on the course of the disease in the individual case. In those cases in which the areas of infarction were very numerous, to such an extent that the function of the kidney was seriously impaired, and when the toxic symptoms were very pronounced, nephrectomy should be the operation of choice. In cases where the infarcts were few in number, to toxemia was mild, and the general condition of the patient was good, splitting of the capsule with drainage of the diseased areas should be considered. Cases were on record, however, in which the symptoms had recurred after this operation and in which a subsequent nephrectomy was necessary.

The Diagnosis and Therapeutic Value of the Renal Catheter.—Dr. K. I. Sanes, of Pittsburgh, stated that the value of the ureteral catheter in the diagnosis and treatment of urological disease was well established. It behooved them all to make use of it more frequently than it had been our custom in the past. To some of us ureteral catheterization seemed a difficult procedure; to others a dangerous one. It should be neither dangerous nor difficult in the hands of men practising surgery. Those who had catheterized many hundreds of ureters had learned not to fear infection from its use, and had gradually extended the field of its application with great satisfaction to themselves and great benefit to their patients.

Renal and Ureteral Calculi.—Dr. Henry Dawson Furniss, of New York city, said that renal and ureteral calculi were more frequent than was generally supposed, and often existed, especially calculi, in the renal cortex for a long time without symptoms. The classical textbook symptomatology of calculi was oftentimes associated with other conditions of the urinary organs. The effect upon the kidney of calculi was dependent upon the size, shape, character, and most of all the location of the stones, those in the pelvis of the kidney and the ureter causing most damage. For those calculi that could not be attacked from the vagina or bladder, the best procedure in stones that would be difficult to locate was the combined intraperitoneal and extraperitoneal operation. If they could be easily found on account of their size, he would prefer the extraperitoneal route. It was not necessary to close the ureter, as it healed rapidly. A cigarette drain near the ureter had best be used for seventy-two hours, or while there was still drainage. If the stones were to be felt through the vagina, they could be removed through it: if impacted in the vesical orifice, by slitting the ureter through an operating cystoscope, or after suprapubic cystotomy, or by cautery fulguration.
Local Anesthesia in Abdominal Surgery with Cinematographic Demonstration.—Dr. Julius H. Jacobson, of Toledo, stated that with this method of local anesthesia he had performed thirty-six operations upon twenty-eight patients, eight of these being operated upon for double hernia. The operations were as follows: Twenty-eight operations for radical cure of inguinal hernia; three operations for strangulated inguinal hernia with radical cure; one operation for radical cure of femoral hernia; two operations for strangulated femoral hernia; one operation for incarcerated umbilical hernia; one operation for incisional hernia. Mortality nil. In only two of the earlier operations was it necessary to finish the operation under a general anesthetic. This was due to inexperience with the method. The operations were uniformly painless, without nausea or vomiting, and without the slightest toxic effect from the anesthetic solution. The sensation of the operation was described by the patient as that of a pulling or tugging on the parts. In a few instances some pain was complained of when working about the hernial sac or peritoneum. This could be overcome by a separate injection of the neck of the sac early in the operation. As the epinephrin acted as hemostatic, there was some danger of a postoperative hematoma. It was therefore necessary to ligate all bloodvessels as soon as they were divided. Cinematographic demonstration showed the complete operation for inguinal hernia under local anesthesia, demonstrating the method of injection, the operation being of the Ferguson type. Motion pictures of local anesthesia of double inguinal hernia, umbilical hernia, and strangulated inguinal hernia were shown.

Operative Treatment of Mammary Carcinoma, with Special Reference to the Pectoral Muscles and Axillary Space.—Dr. Charles Edward Ruth, of Des Moines, said the principal object of his paper was to eliminate all complications resulting from operations upon the mammary gland in malignancy which emptied the axillary space of everything but its vessels and nerves, and thereby exposed them to the grasp of cicatricial tissue which must fill in and close the space, and in thirty-one per cent. of cases caused edema of the arm, and many times intolerable pain with, in no small proportion, practical loss of function of the arm. The operative plan outlined in the paper proposed to eliminate these difficulties by the use of the distal part of the pectoral muscles sutured against the chest wall in such manner as to eliminate entirely all dead space, cicatricial formation, contraction, edema, and gave a result which left little, or no impairment of function in its range, and in no manner increased the danger of recurrence of the malignancy.

Diagnostic Hysterotomy.—Dr. Gordon K. Dickinson, of Jersey City, stated that it was yet a question as to when hysterotomy was justifiable. He had grave doubts whether any one could answer this question in pathological terms. One's personal pride in making a diagnosis without too much surgery should lead to a proper effort to obtain the same through a complete history, curettage, and perhaps the added opportunity of a manual examination of the uterus, but if by these means, particularly in chronic cases, one could not be positive as to the contents of the uterus or of the condition of its substance, then in his opinion hysterotomy was not only justifiable but necessary.

The Use of Iodine in Abdominal Surgery.—Dr. Louis Frank, of Louisville, read a paper on this subject in which he drew the following conclusions: From our work, not only experimentally but from our clinical observations with iodine in the preparation of the field for abdominal operations, we could conclude that while it was effective as a means of sterilizing the skin it had its disadvantages. First, should the intestines come in contact with the iodine, adhesions would undoubtedly take place in the area thus exposed, due to the action of the iodine as an irritant to the peritoneum. Second, when it was used as a means of preparing the field, the utmost care should be taken to avoid such contact by protecting the field beyond the abdominal incision by means of moist pads securely fixed in place. Third, tincture of iodine, judging from experience and experiments, should never be poured into the abdomen.

Dr. John W. Keeffe, of Providence, R. L., read a paper on Stenosis of the Pylorus in Infancy, and reported several cases.

Dr. Arthur T. Jones, of Providence, R. I., reported three cases. One of these was a case of solid tumor of the parovarium evidently originating from the Wolffian body. Case two was one of the large sarcoma of the ovary, with a great amount of fluid in the abdominal cavity. There had been improvement in the general condition of the patient since operation. The prognosis was good for several years in this type of case. In the third case he detailed the results three years after hysterectomy in a case of sarcoma and carcinoma of the uterus.

Sudden Severe Hemorrhage into an Ovarian Cyst Following Delivery.—Dr. William Edgar Darnall, of Atlantic City, stated that ovarian tumors of all sorts and especially cysts, almost always produced serious trouble sooner or later, and especially during pregnancy and the puerperium. The most dangerous period was the puerperium. It was the part of wisdom, therefore, to remove them as soon as they were discovered, if possible.

Cholangitis and Pancreatic Lymphangitis.—Dr. L. W. Swope, of Pittsburgh, reported twenty-two cases out of a series of 2,000 operations on the biliary and pancreatic systems. The clinical histories and physical signs justified the diagnosis of carcinoma of the head of the pancreas. The findings were of such a nature that differentiation from cancer was almost impossible. There was recovery with relief of symptoms after temporary or permanent drainage of the bile passages which excluded the possibility of malignancy. At autopsy upon the three patients who died, the postoperative and post mortem changes were so marked, that the characteristic operative findings were completely altered; consequently post mortem examination had added very little to our knowledge of pancreatic lymphangitis. It was probable that the infection causing the pathological enlargement of the head of the pancreas in these cases traveled through the lymphatics, causing lymphangitis in the pancreatic interstitial tissue. This supposition explained the im-
provement and cure with the subsidence of the inflammatory enlargement of the head of the pancreas which followed operation. The origin of infection was often obscure. Treatment consisted in drainage of the bile passages, temporary or permanent. The former was obtained by surface drainage of the gallbladder and common duct, the latter, by anastomosing the gallbladder to the duodenum or stomach.

Observations Based on Seventy Cases of Bowel Obstruction, with Special Reference to the Unusual Cases.—Dr. Walter C. G. Kirchner, of St. Louis, reviewed his own cases of intestinal obstruction and gave an abstract of the histories of the unusual cases. Obstructions due to hernia were encountered in forty-seven cases or in ten per cent. of the hernias operated on. Most of the cases of ileus were seen in the critical stages, and the mortality rate was fifty-two per cent. In the seventy cases postoperative ileus due to adhesions occurred ten times, with a mortality of fifty per cent. The appendix was implicated in eight per cent. of the cases. Resection of bowel was performed in 25.7 per cent. of the cases, with a mortality of twenty-seven per cent. The intestinal obstructions which were encountered were those caused by adhesions, carcinoma, fibromyoma, intussusception, volvulus, interstitial hernia, excessive dilation of the colon, gallstone, prolapse of intestines through rupture in mesentery, prolapse of intestine through a rent in the omentum, thrombosis of the superior mesenteric artery, etc. Obstruction of the bowel was essentially a surgical condition, and the mortality rate was in direct proportion to the duration of the obstruction. Greater stress should be laid on the necessity for early operation in bowel obstruction. In the early cases of obstruction, resection might be a safe procedure, while in the critical cases primary enterostomy and later resection of bowel or repair of fecal fistula was a better course to pursue.

Cancer of the Uterus and Fibroid Tumors from a Clinical Standpoint.—Dr. Edward Joseph Ill, of Newark, stated that from personal experience he held that fibroid tumors were not a cause of malignant degeneration of the uterus. Among 443 operative cases in his hands there was no record of any fibroid having undergone malignancy, nor was there any record among 2,600 cases recorded in his office case book of any having undergone malignancy, although many of these patients were seen repeatedly for years. The autopsy records of hospitals variously situated showed that from four to eight per cent. of all women over thirty years had fibroid tumors. During the same time that the 443 operations of fibroid tumor took place, he operated in 175 cases of cancer of the uterus. Five of these patients had fibroids in the uterus; four patients were cases of true carcinoma; one patient, with a sarcoma, had small fibroids in the posterior wall, while the sarcoma was situated in the anterior wall behind the scar of an old fixation operation. It was thus shown that all his cancer cases had but 2.8 per cent. of fibroids, which was less than the average of all women over thirty years. His deductions were that they had no right to suggest the operation for removal of fibroid tumors when possible future malignant degeneration constituted the only indication.

The Later Operative Technic in the Treatment of Cancer, with Special Reference to Cancer of the Breast and Uterus.—Dr. Maurice I. Rosenthal, of Fort Wayne, said that it was just as important that the surgeon should appreciate the high degree of infectiousness of cancerous tissue as it was that the practitioner should recognize any symptom which was significant of this disease. The radical operation had demonstrated that infiltrations and glandular enlargements, apparently cancerous, were frequently inflammatory in character, and that cases apparently inoperable by reason of such extensions were readily operable by this technic. As a result of this greater operability, the primary mortality following this greater technic, must be considered when estimating its true value. With the exception of certain epitheliomata, it was in cancer of the breast that something like a reasonable result from operative procedure for cancer was obtained. With some little changes in the technic of this operation, which he described in detail, he had obtained results which, compared with cancer in other regions, might almost be called satisfactory. We might take the technic of this operation, which embodied all that went to make up the operative technic of this disease as a technic typical for operation for cancer in other organs. In his paper he pointed out such steps in the technic as would have a tendency to make the operation more successful, and then reported a series of cases on which he had operated with the results.

Uterine Fibromyomata of the Lower Uterine Segment.—Dr. James N. West, of New York city, reported three cases. The points of interest and instruction in these cases were so numerous that he only called attention to the following: 1. Cases of fibroid tumors of the lower uterine segment occurred with moderate frequency where operation was an immediate and urgent necessity on account of pressure upon the urethra. 2. Cases occurred where fibroids in the lower segment complicated by inflammatory conditions closely resembled malignancy, and that such cases should have the benefit of an exploratory incision. 3. A preliminary myomectomy might often allow the structure to assume a more normal anatomical relation and thus simplify operation and reduce the dangers.

Laceration of the Cervix: A Causative Factor in Salpingitis.—Dr. Francis Reder, of St. Louis, stated that the disclosure of a vaginal examination did not prove definitely the existence of a salpingitis, because the examining finger could not interpret correctly the pain that pervaded oversensitive pelvic viscera. The existence of a hydrosalpinx, when sufficiently large, could usually be diagnosed by palpation without difficulty, whereas a tube that was slightly or not at all distended with fluid would present its difficulties. In a woman who had just given birth to children the most frequent lesion that could be directly attributed to childbirth was a laceration of the cervix. It was a trauma whose importance had been not only too often disregarded, but it had also been underestimated. If the tear was a superficial one, it would most likely heal completely in a short time. If, however, the laceration was a deep and perhaps extensive one, it would not heal. Ever-
sion of the traumatized lips of the cervix would take place, and a chronic inflammatory process with its sequelae would become established. That lacerations of the cervix were the most common atria for infection of the tubes was evidenced by the frequency with which this pathology was encountered during operation. Not only was the infective material carried by the cervical lymphatics to the tubal structures, but it was also deposited into the cellular tissues of the broad ligaments. The necessary surgical measure for relief consisted in freeing the frayed end of the tube, turning back the mucosa and suturing it. Of equal importance was the obliteration of the primary focus by plastic repair of the lacerated cervix. The source inviting microbic inflammation having been removed, infective material would no longer find routes of transmission to the tubes. Freedom from these continued bacterial assaults would gradually permit the tube to return to a normal or almost normal state, with the possibility that the patient might again become pregnant.

Notes on Adventitious Tissues of the Abdominal Cavity.—Dr. Robert T. Morris, of New York city, stated that the Lanie kink, Jackson’s membrane, cobwebs of the attic, and other adventitious tissues of the abdomen, depended upon hyperplasia of embryonic structures already present. The hyperplastic change was brought about by toxic as well as mechanical influences. These tissues were to be differentiated from the adhesions dependent upon toxic injury of endothelial structures. A simplified operation for short circuiting the bowel was described.

Gallstone Surgery.—Dr. Joseph H. Bramham, of Baltimore, reported seven cases, two of which showed the danger of long continued gallstone disease as causing carcinoma. The cases demanded cholecystectomy. In case where the gallbladder was not hopelessly diseased, and where there was no stricture, he had done cholecystostomy. These patients had recovered and usually had remained well. One of his patients has a fistula of long duration which failed to yield to the usual treatment. She went to another physician who closed the fistula with electrocoagulatoin. He found the same thing effectual in another case after other methods had failed. He was persuaded that the gallbladder would be removed more frequently in the future than in the past. The Mayos, who, on account of their enormous experience and wonderful success in these conditions, had done much toward making cholecystectomy the operation of choice. They pointed to the slightly greater mortality of cholecystectomy. This might be accounted for by the graver conditions in which it had been done. They also pointed out that the gallbladder was too small to act as a reservoir, but that probably its function was to relieve tension during the height of liver secretion, and thus prevent regeneration of bile into the pancreatic duct. This was an ingenious theory, yet many animals got on without this organ. Was it not more probable that the small, inadequate gallbladder of man, with its poorly developed coats, was a disappearing organ, physiologically as well as pathologically, very like the appendix?

A Review of the Plastic Methods of Closing the Incisional Herniae.—Dr. Lewis Frederick Smear, of Toledo, stated that the earliest operations for ventral hernia closed the ring without incising even the skin. Later all useless tissue down to the peritoneum was removed and the edges of the ring alone drawn together. Still later the edges of the ring were inverted and the anterior surface of the fascia approximated. Following this, the rectus sheath was opened and the abdominal wall closed in layers. Omphaleotomy was not generally used until after 1888, and the lateral method of approaching the hernial ring was suggested in 1891. Numerous plastic methods of using the fascia and muscle to close the rupture were devised, but the principle of overlapping from above downward had displaced most of them. Tension sutures were used, the hernial ring was attached from within the abdomen, and numerous foreign materials inserted to close the opening, and many important general principles were laid down. At present, the closure in layers or the Mayo operation was used in small hernias, but in the larger ones, if some plastic device was not practicable, we relied upon the filigree. The transplantation of fascia might take the place of the filigree in time and was at present a valuable means of reinforcing doubtful suture lines.

Papers were also read by the following members: Fibroma Cardia in a Girl of Eighteen; Gastrostomy and Entucleation, by Dr. John F. Erdmann, of New York city. Appendicitis in Young Women, by Dr. H. S. Lotf, of Winston, N. C. A Seven Pound Ovarian Tumor That Developed in Nine Days,” by Dr. J. H. Carstens, of Detroit, Michigan. Omentocolopexy, by Dr. H. W. Longyear, of Detroit, Michigan.

Election of Officers.—The following officers were elected for the ensuing year: President, Dr. Charles N. Smith, of Toledo, Ohio; first vice-president, Dr. Hugo O. Pantzer, of Indianapolis, Indiana; second vice-president, Dr. J. H. Bramham, of Baltimore, Maryland; secretary, Dr. E. Gustav Zinke, of Cincinnati, Ohio, reelected; treasurer, Dr. Herman E. Hayd, of Buffalo, New York, reelected. Buffalo, New York, was selected as the place for holding the next annual meeting.

Letters to the Editor.

ENTEROPTOSIA.

173 Lexington Avenue,
New York, September 30, 1913.

To the Editor:

To enteron is the bowel, ta entera (the plural) means the entrails, in Latin viscosa. Enteroptosia is ptosis of the entrails, there exists no Greek one word term for ptosis of the bowels. Another word for entails is splanchon or splanchna, immaterial if we use the singular or the plural. Splanchnoptosia means the same as enteroptosia. Gaster is the stomach, but also the abdomen, and gastrotosia is another synonym of enteroptosia. Ptosis of the stomach alone is stomachoptosia. Compounds ending in is, xia, and pathetic change this ending into ia, except when the first component is a preposition, for instance aspasia—antisepsia; gastrotosia—diagnosis. Some writers do not distinguish between Greek and Latin, employing the hord, the mongrel, the hybrid, the hemophrodite, the illegitimate
term, the bastard word visceroposis. The word atonia means relaxation, it does not signify weakness as some erroneously believe.

It is amusing to learn of all the nonsense and confusion created, even by distinguished writers, who do not know the meaning of these words. Riegel spoke of "simple atony or insufficiency of the stomata. Atony and insufficiency, however, are, as we have seen, not the same thing.

Ptosis of the entrails is caused by atony and atonia gastrica is another synonym of enteroposis. There is no atony of the stomach without dilatation of the stomach. Dilatation of the stomach means delay in movement and comes from fero, ferre, tuli, latum. Dilatatio or dilatation is an abstract noun from dilato, dilatare, dilatavi, dilatatum, to expand, and dilatation is expansion, in Greek ektasio not ectasia as some "hit or miss" will write.

The following two illustrations taken from textbooks will demonstrate the confusion caused by disregard of the true meaning of the words enumerated: "It is impossible to invent a term which shall comprise and connote the important features of all types of motor and mechanical insufficiency, as clear a classification as any is one based on Riegel and Boas, as follows: Simple gastric atony or motor insufficiency or myasthenia without dilatation. Gastric atony is a condition of reduced or lost tonicity of the musculature, sub or hypotonicity, also very aptly designated as gastric myasthenia." Such nonsense in learned sounding language has always been a comic effect, it reminds us of the demonstrator in the dime museum: "Here you see two statues, one of them is Caesar, the other is a monkey, they are very much alike, especially in the neck." "The description in the books of the symptoms of gastroprosis are hopelessly obscure and chaotic, characteristic and diagnostic points are few and these few misleading.

In reality, however, the contrary is the case, there is only one factor and that factor is relaxation, a characteristic point which indicates a rational method of treatment.

These two quotations give us an idea of the confusion brought into medicine by unscientific nomenclature.

ACHILLES ROSE, M.D.

PROTOZOA OR AMEBA OF THE SKIN.

ST. CHARLES HOSPITAL, FORT PIERRE, FLORIDA, SEPTEMBER 15, 1913.

To the Editor:

I wish to report a case that is new to me. If any other doctor has seen a similar one, what were the sequel?

History: Three members of a family were infected by what may be designated General acne developed within a week; indurated noninflammatory; pearly nodules produced very slight itching.

Microscopic findings: Ameba one to four times the diameter of a leucocyte, each containing from one to four nuclei, some vacolated, enclosed in a wall of fibrous tissue and partially degenerated leucocytes. I had expected to find entozoa.

Treatment: Emetin hypodermatically with the local application of a mixture of carbolic acid, camphor, and alcohol, after opening each nodule.

C. G. RÖHR, M.D.

BOOK REVIEWS.

We publish full lists of books received, but we acknowledge no obligation to review all. Nevertheless, so far as service permits, we review those in which we think our readers are likely to be interested.

Next to Kussmaul's Reminiscenzen, Professor Fritsch's Recollections in War of 1870-71 is one of the best biographies written by medical men in the German literature, which abounds in retrospection. Professor Fritsch, for years one of the leading men of the medical faculty of Bonn, has thus compiled a book which is worthy to be placed next to his contributions to the medical science. It is not so much the description of the victorious war that recalls to the reader, but the personal impressions given by the author which at the same time throw an interesting light upon the position of the military surgeon in the army, which has hardly changed during the past four years. The enthusiasm of the German originates not from the victorious gain but from the fact that from 1871 dates the unity of Germany, which has been the dream of generations since 1813. The book will appeal not only to the German reader but to the physician whose science is not limited by political views, but is in reality international.

Doctor Woods has undertaken and succeeded in writing a very interesting book which reveals not only deep thought but as well an enormous amount of historical knowledge. The arrangement of the book has been carefully considered and the text has been well reviewed in its critical. May we return to the main issue, on the page before the appendix, the contents of the matter which appears on the following pages, in such a way, for example, as: France 307; Spain 318, Castile 318, Aragon 325, United Spain 328; Portugal 332. etc. We have done this in the compilation of contents very valuable for reference. There should be, at least to our mind, a somewhat sharper distinction between Charles the Fifth, of Germany and Austria, and Charles of Spain, First, of Spain, who are identical. (See page 83 and page 170.) Furthermore, we do think that on page 60 and on page 316 Marazin should be mentioned. The subject is, as we have said, a very interesting one; that is to observe the histories of the countries with their eras of splendor and decay throw the personality of their rulers. The book shows that only very rarely has a nation progressed in its political and economical aspects save under the leadership of strong monarchs. The author believes that the monarchs have, to a very great extent, caused the change of conditions and not the reverse that the monarchs have been a product of the environment in which they lived. The book makes very interesting reading.

As stated by the author in his preface the object of writing this book was to condense the results of his practice and the labors of other specialists in this branch of medicine. One gets the impression that too much has been attempted in such a small treatise. The field of rectal surgery has grown so large that it cannot be properly covered in a volume of this size. It should be classified as a compendium useful to students rather than as an addition to the literature of the subject of value to the workers in rectal surgery.

The methods of treatment described are in keeping with the best modern practice and, in fact, are described more fully in the various monographs of such specialists as Tuttle, Wallis, Allingham, and Hirschman. The plates and diagrams are well executed and help materially in making the subject clear to beginners in this field.

In the first attention is called to the fact, so often forgotten, that blood changes in leukemia constitute nothing more than a symptom. The increase in the number of white cells may be very slight, and at times may be absent. There will be found, however, young, unripe, and
pathological forms. The characteristic lesion of leukemia is the unusual and well marked pathological hyperplasia of those tissues which form the leucocytes. For discussion the subject is divided into the two common types, the lymphatic and the myelogenous. The first includes the chronic lymphadenoma, the acute lymphatic leucemia chlorolymphephoma, and the aleucemic lymphadenoma. Under the heading of the symptom complex of pseudo-leucemia, lymph nodes of the body is dealt with. Seven excellent plates show the microscopical changes in the different tissues. The book covers the ground quite thoroughly and gives a very clear presentation of the conditions.

This is a well printed book written in the catchy and frank style of the editor of the Critic and Guide. The author gives a good many case histories to show the results of treatment, etc., and one in reading this book is so invariably fascinated with the horrid tales in the case histories that one forgets really what each chapter is about. We can hardly see no means subscribe to all of the author's ideas. For instance, I am sure it would bring endless confusion to the community if the following were the rule, he says: "To advise a confirmed masturbator to get married without being sure of the integrity of his sexual potence, and without his having given proof that he can break himself of the habit at least temporarily, is nothing short of criminal.

It is therefore more honest, more decent, more honorable, more moral, to advise a masturbator to attempt to lead an upright life and maximize the physician's treatment for these cases. It would seem that he would rather prefer to chance a patient getting well, rather than to lead him gently toward the normal path by good sound talk, normal athletics, etc. It would be hard to determine what the lasting mental effect of his treatment for masturbators in children would be. Page 44: "In two or three cases I found it necessary to apply rapidly a red hot iron to the child's genitalia. The child ceased to masturbate."

Die Rassenhygiene in den Vereinigten Staaten von Nordamerika. Von Geza von Hoffmann, k. u. k. östr. Ungar. Vizekonsul. Mit einer Figur im Text. München, J. F. Lehmann, 1913. 116 S., 42 Abb. Under the title of Race Hygiene the author takes up what might more accurately be termed eugenics. After reviewing the underlying factors of eugenics and the dissemination of such ideas in the United States, an interesting chapter is devoted to the regulation of marriage in so far as it affects the well being of the race. The matter of the sterilization of the feebbleminded is also treated quite fully; the various methods and their advantages or disadvantages being referred to. A shorter chapter takes up the topic of the selection of immigrants as carried out in this country. This completes the book with the exception of the texts of various laws relating to the questions discussed and a list of various articles and books that have been used for reference.

Meetings of local Medical Societies.

Monday, October 13th.—Society of Medical Jurisprudence; New York Ophthalmological Society; Association of Alumni of St. Mary's Hospital, Brooklyn; Williamsburgh Medical Society, Brooklyn; Corning Medical School; New Rochelle Medical Society; Waterbury, Conn., Medical Association.

Tuesday, October 14th.—New York Academy of Medicine (Section in Neurology and Psychiatry); New York Obstetrical Society; Medical Society of the County of Schenectady; Medical Society of the County of Rensselaer; Buffalo Academy of Medicine (Section in Medicine); Jamestown Medical Society; Rome Medical Society (annual); Practitioners' Club of Jersey City, N. J.

Wednesday, October 15th.—New York Academy of Medicine (Section in Genitorium Diseases); Woman's Medical Association of New York City (New York Academy of Medicine); Medicolegal Society, New York; Buffalo Medical Club, Northtown Medical and Surgical Society of New York; New Haven, Conn., Medical Association; New Jersey Academy of Medicine, Jersey City, New Jersey.

Thursday, October 16th.—New York Academy of Medicine (stated meeting); German Medical Society, Brooklyn; New York Medical and Surgical Society; Assembled Club, Buffalo, N. Y.

Friday, October 17th.—New York Academy of Medicine (Section in Orthopedic Surgery); Clinical Society of the New York Postgraduate Medical School and Hospital; New York, Buffalo Medical Club; Alumni Association of Roosevelt Hospital; Saratoga Springs Medical Society.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 1, 1913:

Austin, H. W., Senior Surgeon. Granted leave of absence for one month and twelve days from October 6, 1913.

Banks, C. R., Assistant Surgeon. Reassigned duty at the Marine Hospital, Portland, Me., and directed to proceed to Milwaukee, Wis., and assume charge of the Service at that port.

Bolten, J., Assistant Surgeon. Reassigned from duty at the Marine Hospital, Saco, Me., and directed to proceed to Detroit, Mich., and report to the medical officer in charge for temporary duty.

Burkhalter, J. T., Passed Assistant Surgeon. Granted two months' leave of absence from October 1, 1913.

Vorhees, M. G., Passed Assistant Surgeon. Reassigned from duty at Tampa Bay Quarantine Station and directed to proceed to Philadelphia, Pa., for duty in the medical examination of arriving aliens.

Lumaden, L. L., Surgeon. Directed to stop at Raleigh, N. C., for conferences with the state health officer, in connection with field investigations in North Carolina.

Mathewson, H. S., Surgeon. Directed to take temporary charge of the Marine Hospital at Portland, Me., in connection to proceed to New York, N. Y. Reassigned from duty at Gloucester, N. J., and directed to proceed to Evansville, Ind., and assume charge of the Service at that port.

Parker, H. B., Passed Assistant Surgeon. Upon expiration of leave of absence, directed to report to the chief medical officer, Ellis Island, N. Y., for temporary duty.

Preble, Paul, Passed Assistant Surgeon. Directed to report to Assistant Surgeon General J. W. Kerr for temporary duty.

Ridlon, J. R., Passed Assistant Surgeon. Granted leave of absence for two months and twenty days, with pay, and for a further period from December 19, 1913, to January 15, 1914, without pay, with permission to go beyond the sea.

Thompson, L. R., Assistant Surgeon. Reassigned from duty at the Marine Hospital, New York, N. Y., and directed to proceed via Cincinnati, Ohio, to Pittsburgh, Pa., for duty in connection with investigations of pollution of the Ohio River.

Warner, H. J., Passed Assistant Surgeon. Reassigned from duty at the New Orleans Quarantine Station and directed to proceed to the Tampa Bay Quarantine Station and assume charge of the Service at that port.

West, T. J., Acting Assistant Surgeon. Granted two months' additional leave of absence without pay, from September 3, 1913.

White, J. H., Surgeon. Directed to proceed to various places in Louisiana for the purpose of obtaining data and materials for determining the incidence of malaria.

Williams, C. L., Assistant Surgeon. Reassigned from temporary duty at Port Townsend, Wash., and directed to proceed to Washington, D. C. and report to the director of the Hygienic Laboratory for duty.
United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the United States Army for the week ending October 4, 1913:

Ashford, Mahlon, Captain, Medical Corps, relieved from duty of attending at Berwick Ambulance Company No. 1 at Fort D. A. Russell, Wyo., to take effect on the arrival at that post of Captain Wayne H. Crum, and will proceed to Fort Washington, Md., and report for duty. Baker, C. R., First Lieutenant, Medical Reserve Corps. Relieved from temporary duty at Fort Niagara, N. Y., and from further duty at Fort Ethan Allen, Vt., and will proceed to his home in time to arrive there on September 30th and will stand relieved from active duty at the Medical Reserve Corps. Crum, Howard, F., Acting Medical Director, ordered to Fort Cushing, Mass., to take over the duties of attending surgeons in that city until the arrival of Major Russell.

Crouch, George H., Major, Medical Corps. Granted leave of absence for one month, effective upon his arrival in the United States. Crum, Wayn H., Captain, Medical Corps. Upon arrival in the United States, will proceed to Fort D. A. Russell, Wyo., for duty with Ambulance Company No. 1. Davis, W. C., Captain, Medical Corps. Upon arrival in the United States, will proceed to Fort McPherson, Ga., to report in person to the superintendent of the United States Military Academy for duty. Guthrie, William G., First Lieutenant, Medical Reserve Corps. Ordered to active duty and will report to the commander of the Army Medical School, Washington, D. C., for duty. Hamilton, R. M., First Lieutenant, Medical Corps. Granted leave of absence for two months. Johnston, J. F., First Lieutenant, Medical Corps. Relieved from duty at Fort McPherson, Ga., to take effect at such time as will enable him to comply with this order, and proceed on transport sailing from San Francisco, Cal., return to November 5th for Honolulu, H. T., for duty. King, Charles T., Captain, Medical Corps. Upon arrival in the United States, will proceed to Fort McPherson, Wyo., and report for duty. McMillan, C. W., First Lieutenant, Medical Corps. Ordered to Fort Washington for temporary duty. Morse, Arthur W., Major, Medical Corps. Ordered to proceed to Fort Morgan, Ala., for the annual physical examination and test ride. Scott, G. H., Captain, Medical Corps. Ordered to Waterlight Arsenal, on October 7th, for the physical examination of officers at that station and for the examination of Colonel W. W. Gibson, Second Lieutenant, Medical Corps, and Major Colonel, Medical Corps. Upon arrival in the United States will proceed to Boston, Mass., for duty as attending surgeon in that city. Watkins, E. S., First Lieutenant, Medical Reserve Corps. Granted one month's leave beginning the arrival of the Medical Reserve Corps at Key West Barracks, D. C., and report for duty. Whaley, Arthur M., Captain, Medical Corps. Ordered to Fort Howard, Md., for temporary duty in the field.

Woodson, Thomas D., Captain, Medical Corps. Granted leave of absence for fifteen days. Wright, Frederick S., Captain, Medical Corps. Leave of absence for five days.

The following named first lieutenants in the Medical Reserve Corps have been ordered to active duty in the Medical Reserve Corps and to the Army Medical School, Washington, D. C., for course of instruction: L. H. Bauer, L. W. Webb, Jr., R. M. Le Comte, Austin B. Blaum, Walter P. E. Shumaker, Frederick H. Dietrich, Harold H. Fox, and Alexander W. Williams.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending October 4, 1913:

Bass, J. A., Passed Assistant Surgeon. Detached from the Naval Recruiting Party, Erie, Pa., and ordered to the Naval Academy, Annapolis, Md. Curtis, L. W., Medical Director. Detached from the Naval Recruiting Station, Boston, Mass., and ordered to the Naval Hospital, Newport, R. I. Henry, R. B., Passed Assistant Surgeon. Detached from the Naval Hospital, Annapolis, Md., and ordered to the Rhode Island. McDowell, W. N., Passed Assistant Surgeon. Ordered home to await orders. McEwan, W. S., Acting Assistant Surgeon. Detached from the Naval Recruiting Station, Cincinnati, Ohio, and ordered to the Naval Recruiting Station, St. Louis, Mo. Orvis, R. T., Surgeon. Will proceed from Las Animas, Colo., to the Newport Hospital. Plumner, R. W., Passed Assistant Surgeon. Detached from the Naval Recruiting Station, Detroit, Mich., and ordered to the Hancock. Steadman, W. G., Passed Assistant Surgeon. Detached from the Georgia and ordered to the Naval Recruiting Station, Detroit. Strode, H. W. B., Passed Assistant Surgeon. Detached from the Naval Training Station, San Francisco, Cal., and ordered to the Naval Hospital, Puget Sound, Wash. Wilson, H. D., Surgeon. Ordered to the Naval Recruiting Station, Boston, Mass.

Birches, Marriages, and Deaths.

Married

Brigham—McKissock.—In Boston, Mass., on Wednesday, October 1st, Dr. Francis Gorham Brigham and Miss Helen Grecy McKissock. Hurt—Loveale.—In Atlanta, Ga., on Monday, September 22d, Dr. John W. Hurt and Miss Mary Loveale.

Died

Baldwin.—In Rosebank, N. Y., on Friday, October 3d, Dr. Edwin Candee Baldwin, aged forty-eight years. Elliott.—In Kansas City, Mo., on Saturday, September 27th, Dr. Charles Sinclair Elliott, aged fifty years. Fitz—In Brookline, Mass., on Tuesday, September 30th, Dr. Reginald Heber Fitz, of Boston, aged seventy years. Gilbert.—In Nebo, N. C., on Friday, September 10th, Dr. William W. Gilbert, aged seventy-five years. Goldstein.—In New York, on Sunday, October 5th, Dr. Max Goldstein. Harvey.—In Westboro, Mass., on Monday, September 29th, Dr. Edwin B. Harvey, aged seventy-nine years. Hering.—In Westminster, Md., on Tuesday, September 29th, Dr. Joshua Webster Hering, aged eighty years. Kuttner.—In Berkley, Cal., on Sunday, October 5th, Dr. Louis Kuttner, aged forty-seven years. Marvin.—In Muskegon, Mich., on Monday, September 22d, Dr. La Ray Marvin, aged sixty-five years. Michel.—In St. Louis, Mo., on Monday, September 29th, Dr. Charles Michel. Reames.—In Canastota, N. Y., on Thursday, September 25th, Dr. Edwin C. Reames, aged forty-three years. Schenck.—In Flementon, N. J., on Saturday, September 26th, Dr. William H. Schenck, aged eighty-seven years. Shuman.—In Upper Strasburg, Pa., on Sunday, September 21st, Dr. William Britton Shuman, aged thirty-one years. Srodes.—In Woodville, Pa., on Friday, September 26th, Dr. James Louis Srodes, aged fifty-one years. Town.—In Narberth, Pa., on Monday, September 29th, Dr. Edwin C. Town, aged sixty-three years.
Original Communications.

THE CLINICAL FORMS PRESENTED BY NERVOUS SYphilis.

Significance of and Necessity for Their Differentiation.

By F. X. DERCUUM, M.D.,
Professor of Nervous and Mental Diseases, Jefferson Medical College.

The recent developments in our knowledge of the relation of the Treponema pallidum to so called parasyphilis will greatly influence, it would appear, our conceptions of syphilis of the nervous system. The epoch making discovery of the spirochetes in the brain of the parietic by Noguchi has been confirmed by a number of observers, among them Marinesco, Marie, Levaditi and Bankowski, and Poerster and Tomaszewski. The latter have indeed demonstrated the presence of living spirochetes in material obtained from paretics by brain puncture, while Noguchi has successfully inoculated rabbits with the substance of parietic brains, typical syphilitic lesions being produced. The thought that suggests itself at once is that the distinction herebefore made between syphilis of the nervous system, i. e., syphilis of the vessels and membranes, on the one hand, and parasyphilis, i. e., tabes and paresis, on the other, can no longer be maintained, that in truth there is but one affection, that no matter in what forms it presents itself these forms are all nervous syphilis, that the most that can be said is that in syphilis of the vessels and membranes we have an interstitial syphilis and in syphilis of the nerve substance, as in paresis and tabes, we have a parenchymatous syphilis. There is grave danger, however, in attempting to give such generalizations a practical application and great harm may be done in losing sight of important clinical distinctions. While all of the diseases of the nervous system resulting from the infection of spirochetes fall properly under the caption of syphilis, it does not follow that all nervous syphilis is the same, nor does it follow that the clinical distinctions thus far established should be abandoned. Indeed there are many reasons why the latter should be emphasized.

Syphilis of the brain and cord, i. e., gummatous infiltration of the vessels and membranes, presents other things being equal, special symptom groups with special probabilities and possibilities in prognosis. These symptom groups, which are the outcome of the interference of nutrition caused by a diminished hmen or occlusion of the vessels and to a less extent of pressure, it would be out of place to rehearse here; suffice it to say that in syphilis of the brain, the picture is that of headache, somnolence, possibly optic neuritis, or, it may be, palsies of cranial nerves with or without hemiplegia crossed or ipsilateral, while mental symptoms are absent or practically so. Again in syphilis of the cord, the picture is that of a paraplegia in which spasticity and to a less extent ataxia are the dominant features. At the same time there are slight sensory losses—not the retardation of tabes—merely a hypesthesia. Again both the motor and sensory phenomena are unequally marked in the two extremities, one limb is always much more affected than the other. There is also a history of a transient bladder disturbance; first delayed micturition, then slightly lessened vesical control, and lastly and quite commonly spontaneous disappearance of the sphincter symptoms. Finally there is a conspicuous absence of lightninglike, shooting, or other pains. The picture is due primarily to gummatous infiltration of the vessels and membranes of the cord.

How greatly syphilis of the brain and cord differ in their symptomatology from that of paresis on the one hand and of tabes on the other need hardly be pointed out. Paresis in brief presents the picture of a gradually oncoming and slowly increasing dementia which sooner or later terminates in death. Certain physical signs are present but these not only differ largely in kind from those of syphilis of the membranes and vessels but also in being less clearly marked and definite. There are present a variable intention tremor of hands, lips, and tongue, an atactic speech, inequalities, irregularities, sluggishness, or fixation of pupils, the Argyll Robertson pupil, slight modification of gait, spasticity, incoordination, transient apoplectic or hemiplegias, and infrequently transient, slightly marked fungicous pareses of the cranial nerves, and other symptoms impossible to review here, but all of them the outcome of a general, a parenchymatous, destruction of the brain tissue.

In tabes the symptom group again differs widely from that of gummatous disease of the vessels and membranes of the cord. The lightninglike pains, the loss of reflexes, the incoordination, and the Argyll Robertson pupil form a well defined and distinctive picture.

Further, the distinction between the two forms of nervous syphilis, namely the cerebral and spinal symptom groups resulting from gummatous infiltration of vessels and membranes, and the cerebral and spinal symptom groups resulting from disease...
of the nervous parenchyma, so called parasypophilis, was long ago established as the outcome of clinical observation—long before definite conceptions as to the pathology of syphilitic disorders become established or for that matter possible. Clinical observation has not only enabled us to make broad and fundamental distinctions between these cardinal symptom groups, but it has also taught a significant lesson as regards the clinical histories of the patients. Thus, every physician of experience knows that in parasypophilis the history of the original infection, i.e., of the primary lesion, is often difficult to elicit, often denied, and often uncertain. Particularly is this true of paresis; it is almost equally true of tabes, while it is quite the exception in ordinary cerebral and spinal syphilis. In keeping with this a search upon the genitals for scars of the initial lesion is almost invariably met by failure in both paresis and tabes. Again, a history of secondary symptoms, eruptions, mucous patches, sore throat, and falling out of hair, is commonly wanting in parasypophilis (parenchymatous syphilis): if the writer were to trust his own experience entirely, he would say invariably wanting. It is this fact which has led physicians at times to speak of paresis and tabes as the outcome of "mild" syphilis, a designation which is singularly inapt when applied to affections which, as in the case of paresis, are invariably fatal or, as in the case of tabes, attended by gross and permanent destructive changes. What is the significance of this peculiar clinical history? Does it not suggest a possible difference in the character of the infection? How are we to interpret the cases in which both husband and wife suffer from paresis or in which both suffer from tabes? Is it not startling to realize that one of them does not present syphilis of membranes and vessels and the other of parasypophilis, but both the symptoms of parasypophilis? How are we to account for the instances in which a number of men having acquired syphilis from the same woman, all subsequently develop paresis. Morel-Lavallée and Belières have reported an instance in which five men becoming infected by the same woman all became paretic, and to this number Ramadier added a sixth man likewise paretic from the same source. Brosius has reported an instance of seven glass blowers all infected by the same mouthpiece of whom five were attacked by tabes or paresis while the remaining two presented very suspicious symptoms. Similar instances have been recorded by Nonne, by Marie and Bernhard, and by Erb. Certainly it would seem that at times the germs of syphilis undergo some change, acquire some quality which especially favors the development of paresis or it may be that, as Mott has recently suggested, "there may be varieties of spirochetes as there are different varieties of trypanosomes, the morphological character of which would not permit of differentiation." Too little is as yet known of the life history of the spirochetes to say whether the same species may undergo modifications affecting their action upon man, or whether indeed different varieties or even species may not exist at present indistinguishable from each other. Even the biological relationships of the spirochetes have by no means been definitely determined. Schaudinn, who, it will be remembered, discovered the Treponema pallidum, placed it, along with the other spirochetes, among the protozoa. Others, however, and among them Minchin, have pointed out that a trypanosome structure and trypanosome stage are altogether wanting, and that these organisms divide transversely, and not longitudinally, and therefore belong properly to the bacteria.

As opposed to the clinical distinctness and separateness of syphilis of the membranes and vessels and of parasypophilis, it may be pointed out that cases are met with in which symptoms belonging to both groups are present; i.e., that there are cases of paresis in which the evidence also points to syphilis of membranes and vessels, or on the other hand that transitional forms are met with. In the first place, the concurrence of true gummatous lesions in cases of undoubted paresis is excessively rare, and secondly, if cases actually occur in which ordinary cerebral syphilis passes into paresis, it has not been the fortune of the writer in an unusually extensive hospital experience to observe them; indeed the writer believes that they are non-existent or based upon an initial error of diagnosis. A similar explanation applies in the case of the cord. Every now and then a case is reported as one of tabes in which there has been a marked improvement following specific medication; for instance a marked lessening or disappearance of the incoordination together with a return of the knee jerk. Such reports are based, the writer believes, upon a failure to differentiate clearly between syphilis of the membranes and vessels, i.e., a meningomyelitis syphilistica, and true tabes. The common picture presented by syphilis of the cord is that of Erb's symptom group. Here there is in about two thirds of the cases a slightly spastic gait with exaggerated tendon reflexes, but in the remaining third—those cases in which the gummatous infiltration involves mainly the vessels and membranes of the posterior columns—ataxia is present. Sometimes this ataxia is pronounced and at the same time there may be a diminution of the knee jerks which may be so great as to amount practically to a loss. Such a case can very readily be mistaken for one of locomotor ataxia. However, there is not the history of the lighteninglike pains, papillary phenomena are absent or if present consist of inequality, palsies, and dilatation, not of the Argyll Robertson pupil. Perhaps there is also frank involvement of the cranial nerves, or other evidence of cerebral syphilis. Unequal sensory losses, hypesthesias, involving the extremities and slight or transient bladder disturbances may also be present. Such cases, unless they are of too long standing may very readily—and indeed commonly do—improve upon specific medication.

Mercury, the iodides, salvarsan are as powerless in influencing the organic changes in the cord in tabes as they are in paresis. When improvement in a given case follows specific medication, the inference is inevitable that syphilis of the cord and not tabes was present. To state that both syphilis of the vessels and membranes are present concurrently with tabes is virtually a begging of the question. It is conceivable that both in the case of tabes and in that of paresis there are in rare instances also

\[\text{Report on Parasyphilis, Section of Neuropathology, International Medical Congress, London, 1913.}\]
gummatous lesions, but this is on the whole negated both by clinical experience and by microscopic examination.

To repeat, it is necessary to make a clear distinction between syphilis of the vessels and membranes on the one hand and tabes and paresis on the other. The facts of the prognosis of the parasyphilitic affections make such a distinction imperative. Again, the writer believes that it has become necessary to go one step further and to emphasize the distinction between the two great parasyphilitic affections themselves. The clinical distinction between tabes and paresis has of course long been admitted. It is the occurrence of taboparesis, that is, the form in which spinal symptoms appear early, which has tended to obscure the subject. The knee jerks may in such cases be much diminished or even lost. If at the same time incoordination is noticeably absent, the picture of locomotor ataxia may, as is well known, be more or less closely simulated. However, certain striking differences obtain between taboparesis and tabes. In the first place, the history of tabes is one of very slow and gradual evolution. There is a history of difficulty of walking in the dark, of unsteadiness in the mornings while washing the face, of shooting pains more or less severe, of gastric crises, of delayed sensation in the feet and legs, of disturbances of micturition. Early, too, the ataxia becomes a marked feature. Finally, pupillary disturbances make their appearance. These differ notably as we will see from those met with in paresis. Most frequently they consist of a narrowing of the pupils with an early impairment or loss of the light reaction. It is to be especially noted, however, that in tabes the pupils are equal; inequality is excessively rare. Secondly, the impairment of the light reaction is commonly the same on the two sides; sluggishness and the degree of loss are usually not more pronounced on one side than on the other.

In taboparesis, the evolution of the symptoms may be slow, though as a rule it is far more rapid than in tabes. Secondly, mental symptoms make their appearance relatively soon, so that the real nature of the case early becomes apparent. Again, incoordination though present is rarely so pronounced as to play a striking role in the early period. The writer has never in a case of taboparesis elicited as a beginning symptom a history of difficulty in the dark or of unsteadiness in the mornings while washing the face. Shooting pains also form no, or a very inconspicuous part of the early history and at no time do they constitute a prominent or striking feature. Gastric and other crises, it may be safely stated, are excessively rare if not unknown. Delayed sensation in the feet and legs is equally absent: at most a mild hyposthesia, if any, is diffused but not attended by delay as observed. Disturbances of micturition also form no feature of the early history of taboparesis. Again, the disturbances of coordination, though undoubtedly present, are never as pronounced, either early or late as in tabes. Further, the disturbances of the pupil in paresis are peculiar. Long before the light reaction disappears, it is noted that the pupils are unequal, the opposite condition to that met with in the great mass of true tabes. This inequality may be shifting in character, absent at one time, present at another. At the same time it may be noted that one or both pupils are irregular in shape. A pupil may be oval, ovoid, or its circumference may be irregular, the circle may be slightly flattened as by a cord, or it may be slightly angled. This irregularity, like the inequality, is usually changing and shifting, present at times and absent at others, and the pupil may indeed change its shape, while under observation and thus justify the designation “ameboid pupil.” Finally the two pupils may react unequally to light, the reaction may upon one side be prompt and normal, upon the other sluggish or lost. It is perhaps unnecessary to point out that irregularity and the other phenomena just described are rarely, if ever, present in tabes. In the latter changes consist for the most part in symmetrical departures from the normal both in size and light reaction. The reason for this is probably to be sought in the fact that in tabes the myositis and fixation are to be attributed to changes in the cord, while in paresis they are directly due to involvement of the brain—of the oculomotor nuclei and of the intracranial mechanism upon which the shape and movements of the pupil depend. In short, tabes stands in bold contrast to paresis both in its course and final termination. In the great majority of the cases of tabes, the mental condition is good throughout. Many instances could be cited of tabetics who fill important positions, who follow pursuits and vocations which demand not only entire sanity, but often very unusual qualifications. Among them we find physicians, lawyers, business men, men of affairs, and when these patients die, they do not die of a dementia, but of disease of the heart, of the aorta, of an arteriosclerosis, of infections of the bladder, of disease of the kidneys, or of other visceral complications.

The writer is fully aware that some distinguished observers,—for instance Oppenheim,—state that tabes may eventuate in paresis. The writer, however, believes that the points of clinical differentiation are not only sufficient in number, but of such a character as to demand a frank recognition of the two affections as distinct clinical entities. How their occurrence is to be explained is a matter of secondary importance. It may be that it is to be sought for in differences in the infecting organism or differences in the infected individuals. The fact remains, that the wide divergence in their course and prognosis makes their early differentiation of the utmost practical importance.

1710 Walnut Street.

A REPORT OF SEVEN CASES OF SYPHILIS APPARENTLY CURED WITH ONE INJECTION OF SALVARSAN.

BY ABR. L. WOLBARST, M.D.,
New York.

It is nearly three years since the first supplies of salvarsan, then designated by the number “606,” were distributed to selected clinicians for trial by Doctor Ehrlich. In the period that has elapsed, the stage of primary experiment may be said to have been successfully passed, and the remedy is now safely launched and universally accepted, as the
WOLBARST: SALVARSAN.

most potent antisyphilitic agent known to medical science.

The time is too short, to say definitely, whether the wonderfully effective results attained through the use of salvarsan are permanent or only temporary. Relapses have occurred and repetitions of the treatment have been necessary, in the vast majority of the cases treated with this agent, and to all appearances, those who have had most experience with salvarsan have come to the conclusion that the *therapia sterilisans magna* for which we had all hoped so fervently, is yet a thing of the future. That this is still the great desideratum, may be deduced from the statement made by Doctor Ehrlich, in his Address in Pathology before the recent International Medical Congress at London, in which he said that he continually kept in view the idea of freeing the body of microorganisms by one or at most two injections of the proposed remedy, and that in his animal experiments this principle was still being pursued.

In looking over the records of the cases treated by the writer late in 1910, and early in 1911, with salvarsan, administered through the courtesy of Doctor Ehrlich, a number of cases stand out prominently, not only because of the splendid response which they made at that time, but also because of the fact that a cure appeared to have been effected as the result of a single injection. In other words, in those cases, the great aim of a cure with one injection of salvarsan, seems to have been attained, as far as present evidence is able to show.

In any discussion of a cure of syphilis, there are two great factors to be reckoned with. The first is the clinical condition of the patient, and the second is the patient’s serological record as pronounced by the Wassermann test. We are all agreed that if a patient remains clinically well for several years after cessation of treatment, and during the greatest part of that period gives a continuous and persistent negative Wassermann reaction, we may feel reasonably safe in discussing the probability of that patient being cured of his disease. And it goes without saying that any mention of the word “cure,” in reference to syphilis, must always be accompanied by the usual reservations that will allow for the development of future parasyphilitic conditions, and all the other phenomena which are apt to follow syphilis, even in those who appear to be cured of the original disease.

Let us agree, for the moment, on a given state of facts. Let us assume that a patient with undoubted primary and secondary syphilis receives treatment for his disease. Let us assume that after the treatment (of any kind whatever) is suspended, all symptoms of the disease pass off and do not return during a period of at least two or three years. Throughout this period the patient is carefully watched, and the seroreaction studied at frequent intervals. The reaction, positive at first, becomes negative and remains such after repeated examinations. The body weight is increased considerably, and the patient feels better than he ever did. Are we justified in such a case, in declaring that such a patient may consider himself “cured”? The answer must be, yes.

The most recent authoritative “conception” of a cure in syphilis, is that of Wechselmann, of Berlin (Salvarsan Therapy, ii. p. 110), who says: “A syphilitically infected individual is cured if, upon careful and exact clinical examination, he is found to be free from all symptoms of the skin, the mucous membranes, and of all the internal organs, when his serum no longer gives a positive Wassermann reaction, when his lumbar puncture fluid shows no alterations, and if this absence of all, especially these last two most important symptoms, remains permanent upon most careful control throughout a certain period of time which is to be determined according to further experience and observations.” (Urological and Cutaneous Review, July, 1913.)

Another “standard of cure” is given by Nichols (Studies of Syphilis, Bulletin No. 3, U. S. A. Medical Department, July, 1913) as follows: One year without treatment, without any suspicious clinical signs, with several negative Wassermann reactions and no positive ones, and with a negative provocative Wassermann reaction and luetic test at the end of the year.

Nevertheless it is a fact that we are not able to say positively who is, and who is not, cured, notwithstanding our improved methods of treatment and control, and it is just as true to-day as it ever was that the only sure way to tell whether a patient has been cured of syphilis is to wait fifty years after all treatment has been suspended. If the patient has remained well and has had children who have grown to maturity unscathed, that patient has been cured of his disease; otherwise he has not been cured.

But it is apparent that we must adopt some other method of determining this question in a manner that will meet the requirements and feelings of our patients. Notwithstanding our limitations, which, by the way, it is difficult for the average patient to understand, they demand to know when they may consider themselves cured and by what signs they are to know that such is the fact. We cannot tell them to wait fifty years. We must give them something more definite and immediate, and, as a matter of fact, we ourselves require something more tangible than this long look into the future.

It is therefore the writer’s custom to advise patients that if they remain perfectly well for two years after all treatment is stopped, if they gain weight and maintain this gain, and if the seroreaction is repeatedly negative, they may consider themselves cured. At the same time they are impressed with the fact that notwithstanding the apparent cure, there may still be some traces of the disease which our present methods are unable to reveal, and that consequently the disease may nevertheless reappear at any time in the future. They are furthermore told that if the best way to watch for any possible reappearance of the disease, is by having the blood examined for the seroreaction at least twice every year, and that if a positive reaction appears, it must be considered a warning signal that evidences of the disease are likely to make their appearance shortly.

With these conceptions of a “cure” of syphilis in mind, I am prompted to report seven cases of syphilis, which may be considered “cured” with one in-
jection of salvarsan. They have received no other treatment of any kind whatever. They have remained perfectly well, have gained considerably in weight, and four of them have given a persistently negative Wassermann reaction. The remaining three have steadily refused to permit their blood to be taken, for examination, but in all other respects, they may be considered clinically "cured."

A detailed study of these cases will be of interest:

**Case I.** Primary Syphilis. R. E., male, aged twenty-seven years. Referred by Dr. S. W. Bandler. Initial lesion typical, on shaft of penis, near the coronum. Duration, two weeks; no secondaries present; inguinal glands indurated, not tender. November 4, 1910, spirochetes many; Wassermann reaction, positive. November 7, 1910, received 0.5 gramme; "606 hyperideal," intramurally, by the Alt method. Moderate pain, followed by very severe reaction, the temperature reaching 105.4° F. on the ninth day after the injection. This was accompanied by a distinct renal suppression, which was relieved by diuretic measures. Duration, four weeks; no secondaries developed. November 15th, primary lesion gone entirely, except pinkish discoloration and slight thickening of the skin; November 30th, Wassermann reaction ++ +; December 4th, Wassermann reaction +++, skin clear, patient pronounced well. July 5, 1911, recurrence patient reported, continuing perfectly well; there have been no secondaries or other manifestations; Wassermann reaction slightly +; August 7, 1911, condition the same; patient had gained considerably in weight; March 29, 1912, condition perfect; June 6, 1912, condition perfect; Wassermann reaction negative; November 14, 1912, condition perfect; gaining weight; May 12, 1913, condition perfect; gained much weight; Wassermann reaction negative (controlled by three serologists); September 2, 1913, condition perfect; refused another Wassermann test. Period of observation, two years and ten months.

Here, then, we have a case of primary syphilis, spirochetes present, followed by a positive Wassermann reaction, in which one injection of salvarsan was administered and the patient has remained well, without any subsequent treatment, for a period of two years and ten months, with a negative Wassermann reaction and a decided gain in weight and strength.

**Case II. Primary Labial Syphilis.** I. L., male, aged twenty-five years. Referred by Dr. T. Parodi. Chance on upper lip. Duration six weeks, no secondaries; Wassermann reaction two tests, ++; February 14, 1911, received 0.6 gramme; "606," intramurally, by the Alt method. Moderate pain, followed by the disappearance of the lesion within ten days. March 27, 1911, perfectly well, Wassermann reaction —; July 21, 1911, reported feeling well, no secondaries having appeared; August 8, 1911, perfectly well; December 12, 1912, perfectly well; Practitioners’ Laboratory reported as follows: "Since first examination, we have examined his blood every three or four months, and in every instance the result has been distinctly negative." September 3, 1913, Practitioners’ Laboratory reported: "Wassermann reaction —; patient had gained weight and felt perfectly well in all respects. He had taken no treatment whatever since the injection of salvarsan. Period of observation, two years and seven months.

**Case III. Secondary Syphilis, Severe Type.** L. B., male, aged thirty-eight years. Referred by Dr. B. Livingston. Duration, six months. Patient presented a large, deep ulcer on the right lower lip, mucous patches in the mouth and pharynx, and a papular syphilide covering the left side of the face and neck. The patient had been treated with mercury in all its forms, and was salivated several times in the hope of obtaining a recession of the lesions, but without avail. Apparently there was a decided antipathy to mercury for the more treatment he received the worse his condition became. He had lost twenty-four pounds, present weight being 132 pounds. November 10, 1910, he received 0.5 gramme; "606" hyperideal, intramurally, by the Alt method. Moderate pain, so that he remained for several months. He left the hospital ten days later, almost entirely recovered. The ulcer had disappeared, likewise the mucous patches. Since then he had had no treatment of any kind; there had been no recurrence, and he had gained weight continually since the injection. The Wassermann tests had been as follows: December 20, 1910, —; February 1, 1911, —; March 7, 1911, —, and had gained sixteen pounds; May 10, 1911, —; August 1, 1911, felt perfectly well; weighed twenty-five pounds; November 21, 1911, perfectly well, weighed 165 pounds (a gain of thirty-three pounds); December 19, 1912, perfectly well; weighed 172 pounds (a gain of forty pounds); Wassermann reaction (three controls) —; August 12, 1913, patient reported feeling perfectly well in all respects. Period of observation, two years and nine months.

**Comment:** In this case, it will be seen that the patient was suffering from an unusually resistant form of syphilis, in which mercury was of no value whatever. The Wassermann reaction has remained negative for over two years since the treatment was administered, and his clinical condition has been absolutely perfect for nearly three years. In addition he has gained over forty pounds in weight, and all traces of the syphilitic lesions have been eliminated.

**Case IV. Secondary Syphilis.** G. F., male, aged twenty-seven years. Mucous patches involving the mouth and pharynx; duration of disease, four months. Had been unaffected by injections of salicylate of mercury and iumon. Wassermann reaction +; November 22, 1910, received 0.5 gramme salvarsan, intramurally, by the Alt method. Slight pain; patient left the hospital ten days later in excellent condition; all lines of symptoms, perfect condition; gained four pounds; Wassermann reaction —; August 2, 1911, perfect condition, Wassermann reaction +; November 20, 1912, perfect condition, Wassermann reaction —; December 24, 1912, perfect condition, Wassermann reaction —. Period of observation two years and one month.

In the three cases which follow, it has been impossible to obtain a Wassermann test. However, the physical condition of the patients has been under observation from time to time, as will be noted below, and in each case the improvement has been so marked, as to leave no doubt whatever but that the Wassermann reaction, if it could be obtained, would be found negative.

**Case V. Malignant Secondary Syphilis, Resisting Mercury and Iodides.** J. L., male, aged twenty-eight years. Referred by Dr. J. B. Prager, with the following history: Initial infection eighteen months ago; began as a pustule, which grew large and hard, and eventually broke down, resisting treatment for seven months; inguinal glands swollen and tender; six weeks later, the roseola appeared and disappeared only after several months of treatment; for at least three months the patient complained of a sore throat, growing worse all the time, so that speech and swallowing became almost impossible and excruciatingly painful; also had pains in the joints. Examination of the throat revealed a large greenish white ulcerating area covering the uvula, tonsils, posterior pharynx, and part of the roof of the mouth. The mouth could be opened partially, but with great difficulty. Wassermann reaction, in spite of large doses of mercury, + + + + +; November 3, administered 0.5 gramme; "606" hyperideal, intramurally, by the Alt method. No pains or fever. Next day, four hours later the pain became severe and lasted two days. November 15th, patient left the hospital; throat was almost entirely well; was eating solid food. November 25th, three external; patient back at his work, and had gained seven pounds. April 15, 1911, Doctor Prager kindly reported having seen the patient; latter said he was feeling perfectly well, and had gained at least thirty pounds in weight. July 23, 1911, the writer saw the patient and cor-
roborated the report. August 25, 1913, Doctor Frager again kindly reported having seen the patient; he had grown very stout and was in perfect health; had taken no treatment of any kind since the single injection of salvarsan. Period of observation, two years and nine months.

Comment: In this case, as in Case III, mercury and the iodides seemed to be of no avail in stopping the progress of the disease. One injection of salvarsan not only cleared up all the lesions but, for a period of thirty-three months, there has been no recurrence of any kind, the patient has gained at least thirty pounds, and has been in perfect health in all respects.

Case VI. Precocious Tertiary Syphilis. L. C., male, aged thirty-four years. Referred by Dr. M. J. Klein, with the following history: The patient was infected two years previously. Three months later, a severe extensive vesiculopapular eruption developed covering the entire body and face, associated with a gummatus infiltration of the epiglottis and tonsils. The treatment at that time consisted of injections of cyanide, alternating with bicarbonate of mercury, with increasing doses of sodium iodide up to three drachms, three times daily; also local applications to the throat. The general condition was not much improved by this treatment, although the lesions in the throat did subside. The eruption on the face and extremities remained, however, and soon localized itself on the forehead, lobes of the ears, and on the legs and hands. Here there was actual destruction of tissue, which was not destroyed by the treatment. At first, after getting an injection of mercury every second day, and in addition was taking yellow iodide of mercury pills, ½ grain, from nine to twelve daily. At no time did he show any signs of salvation. At various times he also received injections of eposol, biclorid, and sulfanilamide of mercury, and inunctions, all without effect. Wassermann reaction ++. October 12, 1910, received 0.5 gramme salvarsan, intramuscularly, by the Alt method. Had slight pain, which soon disappeared. At the end of ten days, he left the hospital, much improved, and within two weeks after the injection the lesions had disappeared entirely. This patient had not returned for observation, but he had been seen frequently by Doctor Klein, who had kindly reported as follows: August 2, 1911, patient had grown very stout and said he was in perfect health; returned, Nov. 15, 1912. Doctor Klein saw patient, and said he must have gained at least fifty pounds in weight; he felt perfectly well, and had had no additional treatment of any kind. Period of observation, two years and one month.

Comment: This is the third case of this series, in which mercury and iodides were unable to control or benefit the disease; one injection of salvarsan has apparently cured the patient of the disease, and has made the face evident by the long period that has elapsed without recurrence, and by the remarkable gain in body weight.

Case VII. Tertiary Syphilis, with Extensive Syphilitic. Mrs. D. B., aged forty-five years; married twenty-seven years, mother of three healthy children; also had three miscarriages; first noticed bad sore throat six years ago followed by a skin eruption which lasted a week and disappeared. Then took internal treatment. The patient tried this medicine for two years. For one year, was apparently well, but at the end of that time, ulcers began to break out, first on the face, then on the left hand and arm; the face ulcers healed, but those on the hand and arm have remained ever since and have spread quite extensively.

When first examined, she presented enormous crust covered syphilitic involving the left shoulder and arm, and forearm and hand. The Wassermann reaction, ++. January 25, 1911, received 0.5 gramme salvarsan, intramuscularly, by the Alt method. She had slight pain, which soon passed off. Within a few days, the syphilide began to show evidence of improvement, and seventeen days after the injection, the scales had disappeared and healing was well under way. She left the hospital, and since then had persistently refused to present herself for further observation, but her husband had reported on her condition, as follows: June 23, 1911, he stated she was absolutely well, and entirely free from lesions of any kind. August 26, 1913, he stated that she had continued in good health, without a trace of her skin lesion, and had also gained very much in weight. Period of observation, two years and seven months.

It must appear to the unprejudiced student of syphilis and its treatment that, in the seven cases just reported at some length, salvarsan has certainly been the ideal treatment. In each of these seven cases but one intramuscular injection was administered, no other treatment of any kind has interfered with the remedy, and we are scientifically certain that whatever benefit has accrued to the patient must necessarily have come from the salvarsan. Furthermore, in five of the cases, mercury and the iodides were of no avail, and in all of them improvement began simultaneously with the administration of salvarsan.

We therefore feel justified in saying that in these particular cases we have attained the end that has been sought so assiduously by Doctor Ehrlich,—a therapia sterilans magna, a cure brought about by one injection of the remedy. It goes without saying, even at the risk of another repetition, that the word “cure” is employed in the conception mentioned previously in this paper, namely, when the patient shows no clinical evidence of the disease for two years after cessation of treatment, has gained in weight and general health, and, in addition, gives a repeated and persistently negative Wassermann reaction.

Before closing this communication, it would be well to ask whether such convincing results have ever been attained with the intravenous method of administering salvarsan. The writer has given thousands of intravenous injections to many hundreds of patients, and has had the opportunity of observing them carefully for long periods, but in not a single instance has he seen such splendid results as have followed the use of salvarsan by intramuscular injection. Were it not for the pain associated with this method of treatment, it would certainly be the method par excellence. The action of the drug is kept up for a much longer period owing to the continuous absorption and the slower elimination of the drug. In this single factor, above all others, lies the advantage of the intramuscular method. It is for this very same reason that Wechselmann (Münchener medizinische Wochen- schrift, Ix. No. 24, 1913) advocates the use of his subcutaneous method of injection, in preference to the intravenous method.

It would also be interesting to learn the cause for the enormous gain in body weight which these, as well as numerous other patients, have shown, after an intramuscular injection of salvarsan. Undoubtedly, the tonic effect of the arsenic is primarily responsible, but there must be some additional and unknown metabolic action produced by the continued absorption of the drug in syphilitics, which brings about so remarkable a gain in weight. The writer has never seen it so strikingly in patients who have been given the intravenous injections, even though the treatment has been repeated at frequent intervals.
CONCLUSIONS.

In these seven cases, the patients received but one intramuscular injection of salvarsan; no other treatment was administered; they all became, and remained, perfectly well; there have been no recurrences of any kind, and all have gained remarkably in body weight; the periods since the administration of the injection, vary from two years and ten months to two years and one month, an average of two years and six months; in four of these cases the Wassermann seroreaction has been taken repeatedly and has persistently remained negative; it must therefore appear beyond any shadow of doubt, that one intramuscular injection of salvarsan has cured syphilis and may do it again—i. e., remove all manifestations of the disease for several years and produce a persistently negative Wassermann reaction. No other method of treatment has ever been able to show results equally satisfactory. Surely Ehrlich’s ideal has been attained in these cases.

113 East Nineteenth Street.

NEW AND IMPROVED DUODENAL INSTRUMENTS AND TECHNIC OF SPEEDY INTUBATION OF THE NORMAL DUODENUM.*

By I. O. Palefski, M.D., New York.

(From the Gastroenterological Service, Montefiore Home and Hospital.)

On reviewing the literature dealing with duodenal investigation by means of the duodenal tube, it appears to me that the Montefiore Home has not been backward even in this comparatively new science of duodenology, although, heretofore, nothing has appeared in print on this subject from this institution. For over two years, both Dr. S. Wachsmann, medical director of the Montefiore Home, and myself have been actively engaged in the exploration of the duodenum and its contents in both normal and pathological conditions. Indeed, no gastrointestinal case has been considered fully investigated unless accompanied by a duodenal examination.

Some of the predominating features in connection with our studies are:

(a) Improved and original duodenal instruments not hitherto published;

(b) a simplified and accurate technic in the examination of the common digestive enzymes; and

(c) nature and extent of investigations.

These studies were commenced August, 1911, by first inquiring into the laws and principles governing the action of enzymes upon fifty nongastrointestinal cases, thereby acquiring the technic of the examination of the duodenum, simplifying the quantitative tests of enzymes and the establishment of a “standard” of normal duodenal contents. Following these inquiries we have examined the duodenal contents in such common disturbances as anacidity, subacidity, and superacidity; in gastric and duodenal ulcers, achylia gastrica, cancer, arthritis deformans, and diabetes. By means of x-rays in conjunction with the duodenal tube we studied the course of the normal and, subsequently

* Demonstrated before the Harlem Medical Society, New York, February 12, 1913; and before the Section on Medicine, New York Academy, April 15, 1913.
In this preliminary communication, I desire to describe two duodenal instruments, the design and perfection of which are based upon a previous experience and familiarity of the difficulties encountered in a few hundred examinations. It must be remembered that the capsule or ball of the duodenal tube in its way toward the duodenum bears the same relation to the pylorus as the fetal head bears to the pelvis during parturition, namely, that the largest diameters of one must be in relation to the largest diameters of the other. Secondly, to reach its destination, a duodenal instrument must follow the horseshoe course of the duodenum. Hence the smaller and more flexible it is, the sooner will it accomplish its purpose. Finally, in this work the comfort of the patient is paramount. The duodenal tube in general use at present (Einhorn's) reaches the duodenum after from five to twelve hours, and hence it is passed and left over night. This is essentially a cruel procedure and hence refused by most of the patients. Such a diagnostic or therapeutic measure can hardly hope to gain the confidence of many of the members of the profession even to the extent of giving it a trial.

**THE IMPROVED DUODENAL TUBE.**

In order to appreciate its advantages, one must familiarize himself with the disadvantages of the original Gross's and Einhorn's duodenal tubes.

**Gross's Duodenal Tube.** (Fig. 1 A.) It consists of No. 20 French soft tubing enclosing at one end a perforated and calibrated lead ball weighing 160 grains, of the size of a small cherry. The patient swallows the lead ball which reaches the pylorus by the aid of gravity and passes into the duodenum in from two to four hours. However, owing to its bulkiness, patients refuse to swallow it, and for the same reason the pylorus of some patients will not admit it. It already has fallen into oblivion and nothing more need be said about it.

**Einhorn's Duodenal Tube.** (Figs. 1 B, 2 and 3.) It consists of No. 8 French tubing, to one end of which is attached a perforated brass capsule weigh-
ing forty-eight grains. The patient swallows the capsule and, with the aid of a mouthful of water it reaches the floor of the stomach at A, Fig. 2. From this point on, owing to its lightness, its passage into the duodenum depends upon peristalsis, but it is hindered by the coils of the tubing in the stomach. (Fig. 2, C.) At the pylorus, the elongated capsule must undergo rotation by the peristalsis in order to bring its long axis at right angles to the former. (Fig. 2, B.) These features prolong its stay in the stomach, and, not infrequently, it is regurgitated after a considerable length of time. Very often a loop of tubing precedes and enters the duodenum while the capsule remains in the stomach entangled among the coils of the tubing. (Fig. 3.) This is responsible for the many unsuccessful attempts. At any rate, a duodenal examination by its means is wasteful of time as it requires from five to twelve hours. I have employed it long enough to convince myself that, except in rare instances, it is unsuitable for routine duodenal examinations.

**The Improved Duodenal Tube.** (Figs. 1 C, 4 and 5) This combines in itself the advantages and none of the disadvantages of the original tubes. It consists of No. 8 French pure rubber tubing, to one end of which is attached a perforated gold plated lead ball weighing 105 grains. The tube is marked off at 40, 50, 60, and 70 cm. distance from the ball. The following table shows the features of each of the three duodenal tubes:

<table>

</table>

*Disadvantages.

It will thus be observed that the improved duodenal tube is twice as heavy, and its long axis is less than one half that of the capsule of Einhorn’s duodenal tube. It is, therefore, easier swallowed, and by the aid of gravity it reaches the pylorus in a few minutes and gradually makes its way into the duodenum in from one to two hours.

**Method of Introduction.** It is best passed on an empty stomach usually at 9 a.m. Its passage to the pylorus is accomplished in the following three procedures: First, the patient places himself in the recumbent posture with his mouth wide open. The operator introduces the gold plated lead ball directly into the pharynx; the patient then swallows it and assumes the erect posture.

Secondly, the patient now breathes deeply and slowly while the operator is supporting the outer end of the tube. The latter will be seen to move into the mouth until the 35 cm. mark has approached the lips, indicating that the ball has reached the cardinal point. The patient places himself on his right side and the tube is allowed to go into the mouth until the 50 cm. mark slowly approaches the lips. At this point the ball of the duodenal tube passes along the lesser curvature and gravitates toward the pylorus along with the scanty quantity of gastric contents present in the empty or fasting stomach. (Fig. 4.) To ascertain whether the tube has been correctly introduced, the operator aspirates a portion of the gastric contents, which will be obtained only if the ball has reached the pylorus. If no gastric juice is obtained the tube is withdrawn about 10 cm. and then reintroduced, after which aspiration is again attempted until some fluid is invariably obtained. At this juncture I desire to state that the technic just described is applicable to the normal gastroduodenal tract only. It is greatly modified in dilated and pised stomachs, pylorospasm or obstruction, and duodenal obstruction. This will be described fully in the pamphlet. The important points to be remembered during the introduction of the tube are as follows:

(a) The tube should not be introduced further...
than to the 35 cm. mark before the patient places himself on the right side.

(b) If introduced further than the 55 cm. mark there may occur a condition as shown in Fig. 3.

(c) A specimen of the gastric contents must be aspired immediately after the introduction of the tube, while the patient lies on the right side, to ascertain whether or not the duodenal tube has reached the pylorus.

Perhaps the greatest advantage of the modified duodenal tube lies in the fact that its progress from the pylorus toward the duodenum can be watched by aspirating about every half hour and noting the color and reaction of the aspirated contents. Figure 4 shows the duodenum divided into its three anatomical parts, first, second, and third. The following table shows the distance, location of the duodenal tube, and the characteristics of the aspirations at the end of each half hour, in the first two hours after the introduction of the duodenal tube:

<table>
<thead>
<tr>
<th>Distance from lips</th>
<th>Color of aspirated contents</th>

</tr>
<tr>
<td>60 to 65 cm.</td>
<td>yellowish green</td>
<td>Viscid</td>
<td>Neutral</td>
<td>Third portion of the duodenum</td>
</tr>
</tbody>
</table>

The importance of these findings will be elaborated upon in our pamphlet. At present suffice it for me to say that a knowledge of these will enable one to localize lesions in the gastroduodenal tract. It must be remembered, however, that these cannot be obtained with the Einhorn duodenal tube as its passage into the duodenum requires too long a time to watch its progress.

THE IMPROVED DUODENAL ASPIRING BULB.

The methods of aspiration and collection of the duodenal contents has given me some concern. Some use a syringe, others employ Gross's duodenal glass bulb (Fig. 9), both of which make the aspiration of the duodenal contents a tedious procedure. Very frequently, turbid duodenal contents, unsuitable for examination, suddenly appears in the bulb containing previously aspirated clear duodenal contents. The bulb must then be quickly detached and emptied to prevent the admixture of the two portions of fluid. Fig. 10 shows the improved duodenal aspirating bulb with a cock (suggested by Dr. S. Wachsmann). It is seen that the bulb can be readily emptied whenever desired without detaching it.

THE GASTRODUODENAL TUBE.

The findings in a duodenal examination, at times, can hardly be accurately interpreted unless accompanied by a simultaneous examination of the existing conditions in the stomach. Indeed, in certain cases a duodenal examination independent of an examination of the stomach might lead to serious errors. Furthermore, when pathological constituents are present in the duodenal contents, as blood or pus, the question naturally arises as to their source, as these might have been conveyed into the duodenum by the gastric contents. Finally, it was our aim to undertake a series of simultaneous investigations in gastric and duodenal digestion. We have accomplished all these by means of a gastroduodenal tube.

Construction. It is a noncommunicating double channeled tube, one leading into the stomach and...
the other into the duodenum for the purpose of obtaining unmixed gastric and duodenal contents simultaneously. It consists of two lengths of No. 8 French pure gum tubing, sixty centimetres long (Fig. 6, D and G) placed side by side and are covered and held in apposition by a thin drainage tube. (Figs. 6 and 7, E.) The gastric end of each tube is attached to and communicates with a double bored aluminum piece serving as a gastric inlet and duodenal channel, respectively. (Fig. 6, C.) The latter at its other end gives attachment to and communicates with a nine inch tubing (B) holding in suspension a gold plated and perforated lead ball similar to the one described in connection with the duodenal tube. The distance between the aluminum piece and the lead ball equals that between the pylorus and the third portion of the duodenum. (Fig. 8.) The outer ends of tubing D and G are free and separate. (Fig. 7.) The perfection of this tube lies in the fact that it is swallowed, introduced, and retained as readily as the duodenal tube.

**Technic.** The mode of introduction is the same as that of the duodenal tube. Immediately after its introduction the perforated lead ball lies at the pylorus, while the aluminum piece containing the gastric inlet is up in the fundus. When each tube is aspirated by means of a suction bulb and aspirating duodenal glass bulb attached to the outer end of both tubes, gastric contents will be obtained and duodenal contents simultaneously, the operator now introduces, with a syringe, directly into the duodenum or stomach, as desired, liquid foods as milk, white of egg, soup, etc., or medicinal agents, and removes specimens for subsequent examination from time to time.

**CONCLUSIONS.**

In conclusion I desire to state that the invention of the duodenal tube and other duodenal instruments, based upon the same principle, marked the beginning of an era of advancement in gastroenterology, rivalled only by the introduction of the x ray and the invention of the stomach tube. I base my conclusion on the fact that the duodenal tube is capable of reaching a hitherto inaccessible place, yet a depot into which are collecting the contents of the stomach, duodenum, pancreas, liver and gall-bladder.

I desire to express my thanks and appreciation to Mr. L. Farrar, of the firm of Tiemann & Co., and to Mr. William Dunne, photomicrographer to the Cornell laboratory, for the many courtesies shown to me in connection with the designing and perfecting of these instruments.

3390 BROADWAY, NEW YORK.

**THE TEETH AND THEIR RELATION TO THE EYE.**

BY A. MORGAN MACWHINNIE, M.D.,

Seattle, Wash.

Back of every case of eye disturbance there is a physical derangement to account for it. Very many times it is so obscure that one is quite apt to overlook the underlying cause and to confine reasons to local treatment. If it were not for kind Nature, so frequently coming to our aid, many are the patients that we would fail to benefit. We should remember that the underlying cause is of the greatest importance and neglecting its treatment is a very serious mistake that we may, sooner or later, have to cope with in an aggravated form. The exact relationship that accounts for the many eye changes seen, are often due to the obscure conditions of the teeth. I say obscure, for many are the cases that are seen in which no local manifestations of any diseased teeth are evident. Only becoming manifest when the x ray or exploration is used. This relationship, however, has not been definitely established other than clinically. That some relationship seems to have been thought of for a long time, is evident, from the fact that we have the so called "eye tooth" (upper canine, cuspidate). Many are the cases reported of spasm of accommodation, the foundation of which when discovered is in the root of a tooth socket. Ofttimes the spasm is overcome by the use of atropine only to be followed by its return upon the suspension of the mydriatic, the underlying cause not having been sought nor found.

We now realize that the local manifestation and the physical derangement may be widely separated. The exact relation by which the changes are produced in many of the eye cases, is very obscure, the
intervening, or carrying tissue, not apparently suffering in the least. It appears that it is the terminal filaments of nerves or lymphatics that are the carriers, and the lowered resistance at their terminals are occasions for this disturbance.

Several cases were reported by Rogers, where, in filling a tooth, a brooch was left in; this caused hemorrhages of the eye. Temporary blindness has been reported by others. One of the cases which I wish to report is one in which there was a great amount of fatigue, the patient not being able to use his eyes over ten minutes at a time, in which case the teeth were apparently all sound.

Case I. Male, aged thirty-six years. For a period of three years he had never been able to read consecutively longer than fifteen minutes. Any attempt beyond this resulted in a very marked pain in the eye, necessitating a complete cessation of all use of the eyes. He found that by bathing the eyes with very hot water he was greatly relieved for the time being. Under a mydriatic the case was carefully refracted and the appropriate correction given him. In as much as he did not receive the relief desired from this correction, he returned for advice and believed that his glasses were not suited to him. Transillumination of all the sinuses and nasal examination of same failed to reveal any trouble. Refracting him again failed to disclose any change whatsoever in the lenses, and he was advised to consult his dentist regarding the condition of his cuspid teeth. In as much as he had always had his teeth carefully attended to, he very reluctantly sought the advice of his dentist in regard to the teeth. The dentist reported one week later that no trouble could be found with any of the teeth. The blood was examined, the whites, reds, and the hemoglobin index being normal. A thorough examination of the urine failed to throw any light upon the etiological factor. The patient disappeared from any further observation for six months and upon his return stated that he had had no alteration of the symptoms described. Ophthalmoscopical examination revealed the fundus right and left hyperemic, more marked on the left, and the patient persistently insisted that another examination be made in order to determine if a change of glasses was not needed. Refraction, however, gave the same correction as on the two former examinations and I so informed the patient. He was advised to have the teeth again examined and the dentist sent back the same report as previously. He disappeared from view for three months and upon his return there was added to the report, hyperemia of the bulbar conjunctiva well marked but no photophobia. I now insisted that an x ray be made of the superior maxillary, both sides, and to my satisfaction an abscess at the root of the left cuspid manifested itself. The dentist, on this evidence, made an opening above the tooth and reported that the very foulest smelling pus exuded to the approximate amount of 1.5 c. c. The next day the patient was able to read at his pleasure, as long as he desired, and had continued to do so ever since. The patient had not sought any change in the lenses since the evacuation of the pus. He was interviewed recently and had had no further trouble with his eyes. The time elapsed from the opening of the abscess cavity to the present time was three and one half years.

Case II. Male, aged fifty-five years. Four months previously he suffered from a hard attack of lata grippe which laid him off from his work for a period of four weeks. Recovery from the weakness was very slow, and for the last six weeks he had pain described as neuralgia of the right side of the face, extending from the superior maxillary bone to the right eye and car. Vision of the right eye 6/30, left 6/10. Examination of the fundus showed a marked amount of congestion of the retina and optic nerve. He had been a habitual smoker for years, and had no trouble with his teeth so far as he knew. Transillumination showed a dark area over the right maxillary antrum extending to the ethmoid. Although no pus could be demonstrated intranasally, there was a vasomotor condition of the inferior turbinate on the right. Tapping of all his teeth showed none of them sensitive. The application of heat and cold failed to bring out the presence of any tender teeth. By running the finger over the entire area of the gums with moderate pressure, the tissue over the first molar above and below, was more tender than the remaining surface. The first molar (above) was extracted and an opening made into the antrum resulted in the discharge of a considerable amount of putrid matter. Irrigations were used daily, but the patient had no relief from the pain. At the end of the fifth day the first molar (lower) was extracted and inside of an hour there was a complete cessation of all pain, with the return of vision to 6/10 in the right. The hemoglobin had been examined and showed an index of 84. Examination of the lower first molar showed an abscess at its root which evidently was the cause of his excruciating pain. It should be noted that at no time was there any elevation of temperature or pulse.

One can infer from these cases that there is a very intimate relation between the teeth and the eyes. We must keep this relationship ever before us and, whether cavities are present or not, insist that an x ray examination be made in all obscure eye troubles.

604 Leary Building.

PYELITIS IN THE ADULT.*

By CHARLES J. BARTLETT, M. D.,
New Haven, Conn.

Pyelitis is a fairly common disease both in adults and children. It is also one of the easiest of diseases to pass unrecognized. Either it is entirely overlooked or fully or often mistaken for some other condition entirely foreign to the urinary system. In this category are malaria, lumbago, a-

*Read at a meeting of the Connecticut State Medical Society, May 22, 1913.
layed puerperal sepsis, chronic appendicitis, etc. These errors in diagnosis have two explanations. First, a large proportion of all cases of pyelitis have no definite localizing symptoms. This is quite contrary to our usual notions of this disease. Secondly, it is the exception rather than the rule that careful microscopical examinations of the urine are made as a routine, and as long as this continues they are bound to go unrecognized. The necessity for early recognition of the condition is apparent to any one familiar with the appearance of the lesions occurring in the kidney. In an acute pyelitis the destruction of tissue is as a rule slight; the condition may be relieved by appropriate treatment before the kidney parenchyma is deeply involved. In the later stages with the usual complications the organ is beyond repair by any means.

In this paper I shall not limit myself to a discussion of pyelitis in the strict anatomical sense of the term—that is a process confined to the pelvis of the kidney. This is for the reason that inflammation beginning here is not prone to respect the anatomical boundaries of the pelvis. For a time it may be a simple pyelitis, but sooner or later the kidney parenchyma is apt to be involved and the condition becomes a pyelonephritis; and from the clinical standpoint the differentiation between a pyelitis and a pyelonephritis is often impossible. I shall speak only of the disease as it occurs in adults.

The relative frequency of pyelitis is shown by autopsy records. In a study of 20,770 such records from different Austrian hospitals made by Kapsammer, 750 cases of pyelitis and pyelonephritis were found, that is 3.6 per cent. And less than one third of these were correctly diagnosed during the life of the patient. This is evidence beyond question of the frequency with which these cases occurred and were unrecognized, and I believe it is no exaggeration to assert that nearly as large a proportion still go undiagnosed.

I shall first consider the recognition of this condition. For our purpose we may omit that portion of the cases now usually recognized, namely, those in which there are definite localizing symptoms, such as pain and tenderness in the region of the kidney. These are so obvious that they cannot well be overlooked. Such cases, whether complicated by calculus or not, I believe to be decidedly the exception, not the rule. More often the disease appears in one of two quite different forms. In the first of these there is evidence of an acute infection, chills, a high fever which may be septic in type, rapid pulse, and a moderate leucocytosis. The localizing symptoms are lacking or so slight as to be overlooked. For some reason, perhaps by chance, I have seen more of these cases during the puerperium when they are particularly misleading, being naturally mistaken for an infection of the uterus. And I have been surprised to observe in these not only the lack of pain in the kidney region but also the very slight tenderness upon pressure which they show. It may be incorrect to speak of these as acute. Many of them are probably an acute exacerbation of a previously existing unrecognized pyelitis, with a sudden absorption of toxins from the inflamed area. However that may be, the condition is readily overlooked until the urine is examined. And I have found that one cannot always rely upon the statement of the attending physician that the urine shows nothing. I feel safer to examine the urinary sediment myself.

The other type of case is the opposite of this. Instead of the marked constitutional symptoms the process here is so insidious as to be overlooked. The localizing symptoms, if present, are of that indefinite variety which may accompany any one of several different pathological conditions. This is the variety which if noticed at all is liable to go into the category of lumbago, chronic appendicitis, etc. Here, as in the former type, it is the urination which must be the real determining factor in the case. And it is this examination, with its positive findings, which leads to the recognition of a very slight tenderness in the region of one or both kidneys, more often of the right alone.

In pyelitis the urine varies much in different cases, and at different times in the same case. The variation in the quantity of urine excreted, a decrease in the acute cases, and an increase in the more chronic ones, which is usually present, may not be marked and is, of course, not distinctive of this condition. Pyuria is present but it should be remembered that this does not always mean a densely turbid urine with a large amount of sediment. In fact, there may be, at most, but a very slight turbidity and the sediment may be correspondingly scanty. It is only a careful microscopical examination that may indicate the condition present. Another circumstance which is often overlooked is that when pus is collecting in considerable quantities in the pelvis of the kidney in pyelitis, there may be, temporarily, no pyuria provided the condition is unilateral. This is explained by a blocking of the ureter of this kidney for the time by pus, by a calculus, or by a kink in the ureter. For this reason repeated examinations of the urine may be necessary to reach a diagnosis.

Will an examination of the urine in a case of pyuria show, whether the pus is from the kidney pelvis rather than from some other part of the urinary tract? I have been interested in this for some years and do not agree with those who say that this cannot be done. I think that under favorable circumstances differentiation is possible. If there is pyelitis without cystitis this can be dignosticated fairly accurately from the urine. If cystitis is present, it is more difficult to determine whether the pelvis is also involved. There is perhaps no one thing alone in the urine which tells that we are dealing with a pyelitis, but there are several factors which combined may indicate the pelvis as the source of the trouble. The urine in pyelitis is most often acid, though not always. Fewer epithelial cells are present in pyelitis than in cystitis, while the so called tailed epithelial cells are relatively more numerous in pyelitis. I have found red blood corpuscles in small numbers more often in pyelitis. Together with the pus there are liable to be casts of the larger collecting tubules of the kidney, at times containing pus cells, which aid in confirming the diagnosis of pyelitis, together with some involvement of the kidney parenchyma. I think that in the great majority of cases the diagnosis can be
made from the urine. In those exceptional chronic cases in which the urine is constantly alkaline, not due to drugs, but where in spite of this the examination of the sediment is sufficient to indicate the condition to be pyelitis, and a cystitis can be excluded, the presence of a phosphatic calculus in the pelvis may be diagnosed with a fair degree of certainty. Crystals of acid salts in a freshly voided urine giving evidences of pyelitis may indicate a calcium oxalate, or urate, calculus. As already mentioned when a cystitis is present the diagnosis of an accompanying pyelitis from the urine examination is more difficult. It then becomes largely a matter of finding the large tube casts with pus cells which show the involvement of the tubules in the pyramids of the kidney as an extension of a suppurative pyelitis. In the female it is often essential to obtain a catheterized specimen of urine, and in all cases where a bacteriological examination is to be made, it should be obtained and kept under aseptic conditions and be examined while perfectly fresh.

In considering the etiology of pyelitis we may disregard those cases due to drugs or to the toxines of the acute infections, as the cause is here evident and relatively unimportant except as a predisposing factor to bacterial growth. My own results in the bacteriological examination of urine in pyelitis agree with those obtained by others, that the condition is practically always due to bacteria, that the offending bacterium, whatever its nature, is generally present in pure culture, and that the colon bacillus is the organism most often present. The other bacteria which are less often found as the cause of pyelitis are, however, of importance as some of these like Bacillus proteus vulgaris and certain staphylococci are capable of decomposing urine and in this way are factors in the production of phosphatic calculi in the pelvis. In females the colon bacillus is by far the most common invader according to all reports (von Albeck, Lenhart, Brown, Rovsing). In males (Rovsing) it appears to be much less common. And here mention should be made of the comparative frequency with which the tubercle bacillus is the cause of pyuria, from the involvement of the pelvis and lower portion of the kidney substance. Any pyelitis with an acid urine, which cannot be satisfactorily explained by other bacteria present, should be considered as possibly tuberculous, and a careful microscopic search should be made for the tubercle bacillus. It is as a rule not easily found and repeated examinations may be necessary and often animal inoculation before it can be demonstrated.

The presence of such common bacteria as the colon bacillus and the staphylococci as the active cause of pyelitis brings up the question of how they invade the pelvis of the kidney. I shall take but little time in discussing the route by which they reach the kidney. It has been well established that bacteria reach the kidney frequently through the blood, the ureters, and through the lymphatics, at times apparently coming directly through the wall of the colon to the kidney. The ascending route through the ureters is probably much less common than formerly believed. Even when pyelitis is secondary to a chronic cystitis the route may or may not be through the lumen of the ureter. This question of the route of invasion, though of scientific interest, does not appear to me to be of as much importance as are the underlying causes which favor infection of the kidney by the colon bacillus and other organisms. Under normal conditions the urine is germicidal and the epithelial lining of the urinary tract from the pelvis down is resistant to bacteria. The predisposing factors of pyelitis are such as cause a local lessening of resistance to bacterial invasion or such as cause an increased virulence of the organism. Of these the former seems the more important. The most common appears to be some anatomical condition which interferes with the outflow of the urine, and particularly when this interference has already been followed by the development of a cystitis. I need only to mention this, as it is so well recognized as seen in cases of hypertrophied prostate, strictures, etc. The movable kidney with its passive congestion and often compression of its ureter with resulting slight hydronephrosis is not so often considered in this connection as it deserves. There are numerous other factors, only two of which I will mention. The first of these is constipation. As shown by Posner and Lewin the intestinal wall becomes pervious to bacteria in various pathological conditions, and such lesions of the mucous membranes as may occur in constipation may allow bacteria to enter the blood stream. Moreover, the virulence of the colon bacillus is increased in diarrhea and other intestinal diseases. Digestive disorders may thus play a somewhat important part as accessory factors in the production of pyelitis. Another factor is pregnancy including the puerperium. This is always mentioned as one of the common conditions predisposing to pyelitis but is forgotten until impressed upon one by meeting striking examples of it. I happen to have seen several of these cases occurring during the puerperium, mistaken for a late puerperal sepsis, and the error is such a natural one and the symptoms so confusing, that it seems worth while to emphasize the condition here, although I have already referred to it. The patient may have done well following delivery for a few days, but the chart often shows a slight rise of temperature during this time. After a week or ten days or more there is a chill, a sudden rise of temperature to 103° or 105° F., and a rapid pulse, the syndrome of an acute infection but often with almost no localized symptoms. A characteristic finding in these cases is the lack of tenderness in the region of the uterus. Nor do the lochia give evidence of uterine infection. A catheterized specimen of urine at once shows the pyuria and careful palpation on the right side over the kidney will elicit slight tenderness there. This variety of pyelitis most often involves the right kidney. Opitz in sixty-three cases found it limited to the right side in sixty-six per cent.; while Ward, in 187 cases, found the right side alone involved in fifty-five per cent., in ten per cent. the left side alone, and in thirty-five per cent. both sides involved. The greater tendency of the right kidney to be involved is well worth remembering for diagnostic purposes. Cumston, in discussing this infection of the kidney complicating the puerperium, aptly says "this as
many other affections is not diagnosed simply because it is forgotten."

The rational treatment of pyelitis as well as of pyuria in general has been advanced during the past year by the results of studies upon the action of hexamethylenamine. These have come from several sources and have added considerably to our knowledge of the way in which it may be used more effectively in these conditions.

At the meeting of the American Urological Association in 1912, Burnam reported upon a research which he had undertaken primarily to determine the capacity of infected kidneys to excrete hexamethylenamine. The important features of his paper are first, to emphasize what was previously known but not sufficiently appreciated, that this drug is not in itself a germicide at all, but that its germicidal action is due entirely to the formaldehyde set free in its decomposition; secondly, to provide what was lacking before, namely, a simple test for free formaldehyde in the urine in contrast to one for hexamethylenamine; and thirdly, to show that when the drug is given in the small doses usually employed no free formaldehyde is found in the urine in a very large proportion of cases. When five to ten grains were given three times a day, not more than two patients out of ten showed any decomposition of the drug into formaldehyde at all. This was also true when the same doses were given to normal individuals. On the other hand, when twenty to thirty grains were given every four to six hours, over sixty per cent. of the patients showed free formaldehyde in the urine. He emphasized the inference which can obviously be drawn from his results that there is no fixed dose of hexamethylenamine; that in each case this must be determined by testing the urine, and increasing the quantity of hexamethylenamine until free formaldehyde is found in the urine; and that the first toxic effect of the drug is shown by irritability of the bladder and is due to free formaldehyde, and that the dose of this drug may be safely increased until formaldehyde appears.

Tennessee, experimenting with 200 men, was able to confirm Burnam's statement regarding the frequency with which formaldehyde appeared in the urine after the usual dose. These men were divided into two groups of one hundred each. Each man of the first group was given ten grains of hexamethylenamine twice daily and the urine examined at the end of five hours. All but two of the urines were acid in this group, but only forty-two per cent. showed free formaldehyde. In the second group, each man was given twenty grains of the drug in the morning and the urine was examined in two hours. Here fifty-three per cent. were positive; an average for the two groups of forty-seven and five tenths per cent.

The results of other studies on the same topic have since appeared, the latest that of Smith reported before the American Urological Association at their meeting this year. These confirm the value of Burnam's test for formaldehyde and the necessity of increasing the quantity until free formaldehyde appears in the urine. For this purpose the urine should have been recently voided. Burnam's test is so simple that it can be readily used by any one. These studies also show that the sitting free of the formaldehyde occurs in the urine itself, and with one exception agree with Jordan's results that the antiseptic power of hexamethylenamine in alkaline or neutral urine is almost nothing, and that in urine only slightly acid to litmus the decomposition of the drug may or may not take place. Smith and others has found acid sodium phosphate (one half to one teaspoonful directly after meals) the most effective drug tried for rendering the urine acid. By this means he has been able to find free formaldehyde in a much larger proportion of cases than Burnam did.

Because of our lack of any effective urinary antiseptic for use in an alkaline urine the results obtained by Jordan with sandalwood oil in his experimental work are interesting. He found that this drug (twenty minims three times a day) apparently has a selective action upon staphylococci, both in acid and alkaline urine. It has no effect upon the colon bacillus or putrefactive organisms. He did not try its action upon the gonococcus or tubercle bacillus.

The vaccine treatment of pyelitis I shall refer to only briefly. From the use of autogenous vaccines in a limited number of cases I am not enthusiastic over this means of treatment as a cureall. In some cases the symptoms may be improved by the use of such vaccines. I do not, however, recall any case in which the bacterium has completely disappeared under vaccine therapy. I feel that vaccine therapy should not be resorted to until the proper use of hexamethylenamine has proved ineffective. When vaccines are to be used they should always be autogenous, for the different strains of the colon bacillus vary so much that stock vaccines cannot be relied upon. Another point to be borne in mind in the use of bacterial vaccines in general, is that they deteriorate to some extent after a couple of months even when kept cold and, if their use is to be continued longer than this, they should be replaced by a freshly prepared vaccine.

There are numerous phases of this subject of pyelitis which I have not referred to and which I hope will be brought out in the discussion. One of these is cystoscopy, which is often of the greatest assistance in confirming a diagnosis of pyelitis from the appearance of the ureteral openings in the bladder; and it is cystoscopy together with ureteral catheterization which must give the final evidence as to whether one or both kidneys are involved; and this in conjunction with the functional tests of the kidney, now so fully developed particularly by Rowntree and Geraghty, must in the future be relied upon to show whether one kidney if uninvolved can functionate sufficiently for the entire body before nephrectomy is done. I have also omitted discussion of the irrigation of the pelvis of the kidney with formaldehyde or with silver solu-

---

1Burnam's test, as given by him, "consists in adding to the suspected fluid three drops of 0.5 per cent. aqueous solution of phenylhydrazine hydrochloride, and then three drops of a five per cent. aqueous solution of sodium nitroprusside; then an excess of a saturated aqueous solution of sodium hydroxide. It is important that the solution to be tested, as well as the sodium hydroxide, be slightly warmed to a little more than body temperature. When formaldehyde is present in solutions of one in 20,000, or stronger, an intense blue color appears, which gradually changes to green, and then after a few minutes to brown. In solutions of less than one in 20,000 the first color is an intense green which passes off into a brown. The test is delicate down to one in 150,000 or less."
tions for therapeutic purposes; also the recent method of pyelography by means of the x rays after dilating the pelvis with collargol in determining the extent of the kidney destruction and the degree of dilatation of its pelvis. Though very valuable, these are works to be done by specialists.

The few things that I have been impressed with in studying pyelitis is the frequency with which it occurs and is overlooked, the ease with which it is recognized by simple methods available to all, and the greater chance for improvement or cure if these cases can be recognized early. And it is these points which I wish to emphasize.

THE MENTALLY DEFECTIVE IMMIGRANT.

BY BERNARD GLUECK, M.D.,
Ellis Island, New York.

Acting Assistant Surgeon, United States Public Health Service.

The problem of mental defectiveness, in so far as it relates to the administration of our immigration law, is a peculiar one.

Section one of the immigration law provides among other things, that all idiots, imbeciles, and feebleminded persons shall be excluded from admission into the United States. Further than this the law does not take upon itself to define these conditions, and a rational carrying out, therefore, of the provisions of this law implies the existence of a common understanding as to the meaning of the terms idiocy, imbecility, and feeblemindedness as symbolizing definite, well characterized mental states. For this reason any rational approach to this problem must have as its starting point the question of definitions. For practical purposes we may confine ourselves in this discussion to the term feeblemindedness, inasmuch as the terms idiocy and imbecility are intended solely to convey the idea of a more profound grade of mental enfeeblement.

Furthermore, no great difficulty need be encountered in reaching a common understanding concerning the meaning of the terms idiocy and imbecility. These conditions are so well characterized symptomatically, the idiot and imbecile differ so essentially from what is generally conceived to be a normal human being, as to cause no diagnostic difficulty. Even in our work among immigrants no difficulty should be encountered in diagnostiating these conditions. The Russian idiot is not likely to impre us very much different than the Italian idiot. It is, however, a very much different situation when we come to consider the feeblemindedness.

What then is meant by the term feeblemindedness? We might safely assume that to the minds of most of us this term conveys a more or less clear concept of a state of mental enfeeblement or defectiveness.

Such a concept, however, does not necessarily signify a knowledge of the nature of the condition thus spoken of. It is merely an abstract idea of the meaning of this symbol. We may go a step further and say that some of us when using the term feeblemindedness have both an abstract conception of a certain state of mental enfeeblement and a knowledge of certain characteristics which by common consent are wont to be considered as indicative of feeblemindedness. Still a mere knowledge of these characteristics and the finding of them in a given individual is not sufficient to justify a diagnosis of feeblemindedness. For it is not primarily the condition as such that we are endeavoring to diagnosticate, but the personality, the feebleminded person created by this condition. Defective attention and memory and a diminished capacity for constructive imagination, or a lack of this capacity, are given as some of the characteristics of the feebleminded. Still the finding of these conditions in an individual is certainly not sufficient to justify a diagnosis of feeblemindedness. The mental processes concerned in enabling one to reach a conclusion in a given case must embrace a sizing up in toto of the personality created by these anomalies and defects, and a comparison of this personality with a mental picture of that which constitutes a normal man. Obviously, therefore, a knowledge of the normal mind, of the infinite possibilities for variation within the range of normal, of the various determining factors, such as race, age, sex, degree and kind of formal education, the complexities and variations in the mental, moral, and physical environments, factors which play their parts in bringing about these variations in what is still normal man, must be had before an attempt is made to diagnosticate the abnormal.

As in other fields of medicine, we must have a clear conception of the physiology—of the normal state of an organ—before any rational attempt can be made to evaluate the pathological phases of that organ. But while these problems have been solved to a large extent for most of the functions of the human organism, the human mind, that most complex of all body organs, is still as much of a riddle to us as ever.

'Tis true we have solved many problems in this field of biology. We have succeeded in isolating a number of the constituent factors which enter into the production of normal thinking, feeling, and acting. We have learned a good deal concerning the parts played by volition, attention, memory, apprehension, etc., in bringing about that exquisite whole which constitutes a rational human being, still when we are asked, for instance, what constitutes a normal mind we shall encounter almost insurmountable difficulties in defining it. The best we can do is to say the normal mind is the usual, the common, the everyday mind as we encounter it determining the
usual, the common, the everyday human conduct and behavior.

To attempt a more precise or exact definition of the normal mind would be useless. For although experimental psychology has demonstrated the possibility of applying instruments of precision to the investigation of mental functions, the human mind, and by that I mean that sum total of mentation which constitutes personality, individuality, can neither be weighed nor measured and, not being able to analyze it with any degree of precision, it still remains more or less of a mystery to us and therefore indefinable. And yet, every one of us has some sort of conception of what constitutes normality in a human being. Empirically, we have learned to reason that that organ which performs the functions it was destined to perform in a proper, adequate, efficient manner must be looked upon as normal. Applying this mode of reasoning to the human mind, we would say that in the business of life that human being who goes through life with the least amount of friction, with the most efficient capacity for an adequate adaptation to the environment in which he happens to be placed, and who possesses the elements which enable him to so modify his immediate environment as to make it productive of the most good to himself and the community, or as has been tersely put by Dr. David Starr Jordan, "that individual who can take care of himself and have something left over for the common welfare," that individual we must look upon as normal. Even this definition has its limitations and objections. In considering the human mind as a whole, as an organism in its relation to its environment, we cannot speak of absolute but only of relative values.

At all times, we must keep in mind the infinite possibilities for variation within the limits of normality. At all times we must likewise keep in mind the various factors enumerated elsewhere, each of which plays its distinct part in making man just what he is. The definition given above will suffice, however, for all ordinary intents and purposes; at any rate, it will give us a working basis for a clearer understanding of what might be meant by the term feeblemindedness. Keeping this definition of normality in mind, we shall, in our efforts to detect the abnormal, use as a criterion the individual's capacity to fulfill those requirements.

It will be seen, then, that primarily any definition of feeblemindedness must be a social one, and in line with this several workable definitions have been evolved. The one adapted by the British Commission for the Study of the Feebleminded is perhaps as good as any—namely, the feebleminded are individuals who on account of incomplete cerebral development are unable to perform their duties as members of society in the position of life to which they were born. In this manner has been defined the pathological state commonly known as feeblemindedness, but unlike in the realm of the physical, we were not enabled to reach this definition by means of experimental investigation. It was Nature's experiments in Nature's own laboratory, the everyday life about us, which gave us a clue to this definition. It is for this reason that we term it a social definition in contradistinction to the artificial one of which we shall speak presently.

As our interest in the subject of feeblemindedness increased, and as we began to realize more and more the importance of this problem in relation to the ultimate welfare of the race, an attempt was made to improve upon Nature's crude and often cruel method of pointing out to us the feebleminded. It was felt that if the feebleminded individual could by some means be detected before his deficiency was manifested through an inability for a proper adjustment to his environment, an untold lot of suffering could be spared both the individual and the community. There was only one way of doing this, namely, the creating of an artificial environment with its artificial complexities and problems, the subjecting of the individual to this artificial environment, and the observation of how efficiently he adjusted himself to it, and how successful he was in solving its problems. In other words, it was in a way an attempt at emulating the laboratorian's method of reaching a diagnosis, and as the latter must have a conception of the normal, the usual, the physiological, before he is able to recognize the pathological, so here the normal, the average, the physiological, if you please, in adaptation to this artificial environment must be known before we are able to recognize the abnormal. All tests devised for the examination of the feebleminded rest upon this principle, and the value of any one of them is in direct proportion to the amount of knowledge we possess concerning the normal average individual's ability to solve it. It is here where the psychologist and his fellow investigator in all other fields of medicine begin to diverge. For the anatomist or physician it is sufficient to learn what constitutes a normal human heart or kidney or liver to be able to pass judgment upon all variations from the normal in every other human heart, kidney, or liver. Not so with the psychologist who deals with the human mind. He may by the process already outlined succeed in finding out what constitutes the normal mind or intellect or intelligence of the average child of a given race and a given age; this by no means tells him, however, what the normal, average mind or intelligence is of every other child of the same age. The human mind is at any given period the end result of all the moral, mental, and physical influences to which it had been subjected, all of which played their part in making it just what it is. This is what determines the differences between peoples, between races. It is this which makes for the distinction between the average American of to-day and the average African savage.

Thus any artificial definition of feeblemindedness can only be considered dependable when viewed from this standpoint. Artificially, we can only define feeblemindedness in that group of people, in that particular race, whose average intelligence we know and are able to use for comparison. It would be utterly absurd, for instance, to use what represents the average normal intelligence of the American as a means of detecting the feebleminded African savage. Not that essentially feeblemindedness in the African savage differs from feeble-
mindedness in the American. The difference lies in the means of detecting the condition, in the standard for what represents the average normal mentality used for comparison. Viewed from the standpoint of the average normal intelligence of the American, whole tribes of African savages might easily be considered feebleminded, yet if we consider the situation from the standpoint of social definition of feeblemindedness the average normal individual of these same tribes of savages is able to perform his duties as a member of society in the position of life to which he was born. At best any artificial definition of feeblemindedness can only serve to augment the social one. It can never supplant it. It can only be relied upon when employed within the limits of its usefulness.

Just along these principles is based the so called Binet-Simon measuring scale of intelligence which appeared in 1908, and which in the words of one of Binet’s most enthusiastic followers, has proved to be a most marvelous measure of the intelligence of the child. The nature of these tests is so well known as to require no special description here. The standard of intelligence this measuring scale represents was obtained from an examination of a number of French school children, and so far as we know, originally at least, it intended to represent the average intelligence of French children. Since then Goddard and others have succeeded in elaborating an American modification of this measuring scale.

The principle upon which these measuring scales of intelligence are based is a correct one and, without entering into a detailed discussion of the subject, we are inclined to concede their dependability at least as far as French and American children are concerned, especially when we note the tremendous popularity which these tests have attained in this country, and the degree of reliance placed in them by a number of our most eminent investigators in this field. Nevertheless, a great deal of adverse criticism has been directed against them from many quarters. Some of this criticism is absolutely justified, and all of it, to my mind, was provoked through the attempt on the part of some of the followers of Binet to supplant entirely the social definition of feeblemindedness by this wholly artificial one. It is hard to conceive how this will ever be accomplished, how the mere inability of an individual to pass a certain set of tests will ever be looked upon as absolute proof of feeblemindedness. The experiments herein reported illustrate some of the difficulties in this problem. Several years ago, however, the following terminology was adopted by the American Association for the Study of the Feebleminded: 1. Idiot, mental age below two years. 2. Imbecile, mental age between two and seven years. 3. Moron, mental age between seven and twelve years.

The foregoing is based upon mental ages as represented by the Binet-Simon scale. We shall leave the decision as regards the correctness and reliability of this terminology to those particularly interested in mental defectiveness in American institutions, for after all the chief value of a classification which leaves out entirely the consideration of the social definition of feeblemindedness can only be a means of classifying the inmates of an institution.

Ours is the problem of the immigrant, and since an attempt has been made by some of the followers of Binet to detect feeblemindedness among immigrants by means of their measuring scale of intelligence, we shall have something to say concerning this phase of the problem. Since our immigrants belong to a large number of races, who come to us from practically all parts of the world, and since it was attempted to diagnosticize the feebleminded from among all these races by means of the Binet-Simon scale, and since further we know that a diagnosis by artificial means of feeblemindedness consists in a comparison of the individually intelligence with a given standard of average normal intelligence, it may be safely assumed that these investigators considered the Binet-Simon scale of intelligence as the standard of the average normal intelligence of all these various peoples which furnish our immigrants. Is this so? Does the Binet-Simon measuring scale of intelligence or its American modification, evolved as these were from French and American children, represent the average normal intelligence of practically the entire human race? Assuredly not. We are convinced of this both from experience with the immigrant and actual experimental investigation of the subject, and were it considered necessary to adduce facts to prove the fallacy of such a contention, these could easily be gotten from the hundreds of case histories on file at Ellis Island. No such proof, however, is deemed necessary. The Binet-Simon scale was never intended to assume such wide spheres of usefulness and application. Binet to my knowledge, never stated that it represented anything but the average normal intelligence of the French child. We are told that it accomplishes this, and are inclined to think that as far as it goes it does represent what might be taken as the average, the ordinary, the everyday intelligence of French children. We may say that viewed on a Parisian boulevard, the average French school child or the intelligence it represents, is the average, the common, the everyday occurrence in this particular environment. But we may just as safely say that this same French school child or the mentality which it represents, viewed in some provincial town of southern Italy, would be quite the unusual, the uncommon, the rare in this particular environment.

I have before me the case history of a thirty-five year old Southern Italian who was picked from the examining line on the suspicion of being mentally defective. Confining myself to that part of the history which deals with tests similar to, and in some instances identical with, those of the Binet-Simon scale, I find that at most this particular individual could be placed somewhere between eight and ten years of age mentally, and thus would have to be classified at least as a moron. On further scrutinizing this history, I find that this individual had been in the United States on a former occasion for two years, that he worked as a common laborer at $1.75 per diem, that during this period he sent home for the support of his family 2,000 lire, approximately 400 dollars, and that on returning home after the expiration of his two years' res-
In this country, he took with him 2,000 lire more. I further find that he is married, is the father of two children, owns some property in Italy which he acquired with the aforementioned savings and that his chief object in returning to this country is to repeat what he had done once before. I have no doubt that he will succeed in doing this, and without going into further detail of this case I am very strongly inclined to doubt the value and dependability of the findings of the first part of this history. I am inclined to assume in this case the existence of strongly presumptive evidence that this particular individual is not feebleminded, basing my conclusions on those facts which point conclusively to this individual's ability to lead a normal life and take his place properly as a member of society in the position of life to which he was born. In other words, having the choice of the two definitions of feeblemindedness, I base my conclusions on the social one in preference to the artificial one.

It is the only rational way of approach to this problem if we believe, and we are justified in doing so, that any artificial definition of feeblemindedness can only serve to augment the social one, that it can never entirely replace it, and that being based upon artificial results a definite idea of the average standard with which these results are to be compared must be had, before any rational conclusion can be reached in a given case.

We have seen thus far, therefore, that in our efforts to reach a common understanding concerning what constitutes feeblemindedness, we have evolved two modes of defining this condition—namely, a social one, having as its criterion the individual's ability for a proper fulfilment of his tasks as a member of a given society, and an artificial one having as its criterion the individual's ability to solve a certain set of artificial problems. We have endeavored to point out the respective values of the two, their usefulness and limitations, and it now remains to see how far these considerations can be applied to our problem. i. e., to the carrying out of the provisions of the immigration law so far as these concern the mentally defective immigrant.

Before doing this, however, it is essential to point out the nature of our problem, its peculiar characteristics and the various points wherein it differs from the problem of mental defectiveness in general. During the fiscal year ending June 30, 1913, something like 900,000 immigrants entered at the various ports of this country. Upon the officers of the United States Public Health Service devolved the tremendous problem of picking from this vast army of people, among others, the feebleminded, imbeciles, and idiots. These people come to our shores as total strangers, no information aside from that embodied in the manifest sheet, which by the way is not obtained for the benefit of the medical officers, is had concerning them. Whatever medical examination was done had to be done essentially and primarily in a more or less objective manner.

The practice of psychiatry at a port of entrance, therefore, has very little in common with the practice of psychiatry in general. Here, unlike in general practice, attention to a mentally diseased or defective individual is not attracted through some insane act, or through the inability of the individual to adjust himself to his environment, data without which no psychiatrist would consider himself justified in finally passing upon a given case. In our work such presumptive evidence of mental defectiveness or insanity is entirely wanting.

The examining officer must content himself with merely observing the passing stream of humanity and picking from among them, for further examination, those whom he suspects of being mentally diseased or defective.

The work, then, broadly speaking, divides itself into two parts. The first is the primary picking out of those suspected of being defective, while the second consists in the final diagnosis of those so put aside. Concerning the former we shall have very little to say, beyond commenting on the really remarkable degree of efficiency in objective diagnosis which obtains among the medical officers at Ellis Island. During the past fiscal year, for instance, the large number of between six and seven hundred mentally defective and diseased immigrants were detected at this station, primarily, almost wholly, by this purely objective form of diagnosis. These figures can only be properly appreciated when one is acquainted with the almost insurmountable difficulties under which this work has to be accomplished.

The real difficulty, however, begins when the final diagnosis of the suspected cases is to be made. As we have already indicated elsewhere, no great difficulty should be experienced in diagnosing the idiot or even the imbecile, but what of the feebleminded?

This twilight state between day and night, this borderline mental state which stands between the absolutely fit and the absolutely unfit is by no means easily diagnosed. We must remember that here we are not in the least assisted by Nature in pointing out to us the defective, we have no means of any reliability concerning a social definition of feeblemindedness. We must therefore depend wholly upon an artificial definition of this condition. What means have we of doing this? What, if you please, constitutes the yardstick by which these people are to be measured? We hope that we have succeeded in showing that the various measuring scales of intelligence cannot be of any assistance to us, aside from pointing out to us the modus operandi whereby we might establish some dependable standard by which to measure the immigrant. We must create for these people an artificial environment, with its artificial complexities and problems, and observe what is the average normal way in which the immigrant should solve these problems. What will eventually constitute the standards evolved by these means cannot be foretold, but if they are to be carried out on the principle that artificially we can only define feeblemindedness in that group of people, in that case whose average normal intelligence we know and can use for comparison, there can be little doubt that whatever the standard will be it will at least be a dependable one.

We cannot enter here into a detailed discussion of the way in which this is to be accomplished, besides the experiments herein reported will in a
measure indicate the mode of procedure, but we might state that any set of tests which might eventually be evolved will have to reckon with the elements of time and language, and will have to take into consideration the mental state of the immigrant upon his arrival to this country.

Where hundreds and not infrequently thousands of people have to be inspected daily, and where at least even under the most conservative estimate one per cent. of those inspected should be examined in detail for mental defectiveness, the time element necessarily assumes tremendous proportions, and no set of tests will be absolutely desirable which will require a large amount of time for carrying them out.

The hundreds of thousands of immigrants which come to our shores annually speak an untold number of languages and dialects, and practically the only route through which access may be had to an individual's mentality, language, is closed to the examiner unless he is able to speak the alien's language. Dependence upon interpreters is very undesirable in the carrying out of this work, I am convinced of that. The tests, therefore, should be as far as possible performance tests so as to eliminate to the greatest possible extent the element of language.

One must have been actually engaged in the work among immigrants to adequately appreciate the importance of taking into consideration the mental state under which the alien is laboring upon arrival to our shores. The state of apprehension, anxiety, and severe fatigue, from which many of them suffer on arrival, must be reckoned with if our data on which to base a diagnosis are to be dependable.

In the experiments herein reported it was attempted to follow out in a general way these outlined principles. Unfortunately the work had to be performed under a good deal of difficulty, and for that reason among others the results obtained, while throwing some light upon this important problem, are far from having solved it. Certain phases which should have been investigated, unfortunately, had to be omitted, and the number of subjects used is hardly sufficient to justify the drawing of any definite conclusions. The tests used, while in the main proper ones, could likewise be much improved upon.

NATURE OF THE EXPERIMENT.

At the outset it was felt that if a correct idea was to be gained of the average normal intelligence of a given race, only such individuals should be tested who were as far as possible free from the benefits of artificial purposed education. It was the average native ability which was sought. For this reason fifty individuals, who in their outward appearance suggested nothing abnormal, were picked off at random from the inspection line. None of them had ever attended school or knew how to read or write. They were between the ages of eighteen and forty, and, in this instance, of the Polish race.

The material used consisted of the following series of tests:

1A. Questions intended to bring out the mental stock of the individual tested.
B. Tests of pure intellectual capacity.
C. Associative ability, i.e., tests intended to bring out the individual capacity to grasp a rather unusual experience by means of new mental associations.
D. Tests of ability to acquire new knowledge.
E. Orientation.
F. Recent memory.
G. Discriminative ability, and ability to perceive differences in size and form.

SERIES A.

1. Number of months in the year.
2. Names of the months.
3. Number of days in the year.
4. Number of days in the week.
5. Name the days of the week.
6. Number of weeks in a month.
7. Name of the Capitol of native country.
8. Name of the ruler of native country.
9. Names of the native coins, and number of units in the piece.
10. Number of the commandments of God.
11. Significance of Easter.
12. Ability to tell the time by a watch.

The results from the examination of the fifty immigrants in this series were as follows:

The results from this series serve to illustrate how profoundly ignorant some of these individuals were, and yet we had convinced ourselves by means of exhaustive examination that none of these particular individuals were feebleminded. It seems that these people, limited as is their opportunity for acquiring an education, confine themselves to the acquisition of those facts which are absolutely essential in their struggle for existence.

The question of the relation of ignorance to feeblemindedness is a difficult one to decide. The facts which we possess would seem to indicate that the relation, if any exists, is but a slight one. The figures of the last United States Census for the State of New York are interesting in this connection. These figures show that while the illiteracy of the foreign born white population is 13.7 per cent., that of foreign or mixed parentage is only 0.7 per cent. These figures are very enlightening, especially when we are told in the same report that the illiteracy of whites of native parentage is 0.8 per cent., or 0.1 per cent. higher than in children of foreign or mixed parentage. This shows that what most of the illiterate immigrants need is an opportunity for acquiring an education, and that the fact that they are illiterate upon arrival to this

With but slight modifications, the tests used were taken from a list prepared by Dr. E. H. Mullan, United States Public Health Service.
country does not necessarily have any bearing upon their intellectual capacity. On the whole we are convinced from our own experience with the immigrant that tests which intend to bring out the intellectual stock, or the amount of knowledge a given individual possesses, are of very little value in this work, unless we are dealing with one who has had the benefits of a formal education. Even in the latter case one must be cautious in reaching conclusions based upon the amount of facts an individual has been able to retain. The emotional value of the facts in question must be taken into consideration, as well as the length of time elapsed since their acquisition. It is one of the chief safeguards of the human mind to forget things which have no particular effective value.

SERIES B.

Pure intellectual capacity.

Number.

1. $5 + 4$. 2. $7 - 9$. 3. $2 + 3 + 4$. 4. $15 - 17$. 5. $5 \times 3$. 6. $4 \times 7$. 7. $10 - 7$. 8. $12 - 5$. 9. $18 - 7$. 10. What number added to 2 makes 15? 11. Divide 20 apples into 4 equal parcels. 12. How many legs have 3 horses.

SERIES C.

Associative ability.

No. 1. Name the days of the week backward.
No. 2. Count backward from twenty to one.

Of the two questions under this series, the former was answered by all of the individuals examined, i.e., 100 per cent. correct, while the latter was solved correctly by forty-two out of the fifty, or ninety-two per cent. correct.

The results of series B and C, illustrating, as they do, primarily intellectual capacity, serve to further emphasize my contention that the stock of knowledge an individual possesses, even when one confines himself to everyday common facts, is no criterion of a person’s intellectual capacity. The average correct percentage of answers to series A (questions testing the intellectual stock) was 80.16, while that to series B and C (questions of intellectual capacity) was 85, a considerably better showing.

SERIES D.

Ability to acquire new knowledge.

No. 1. Name of the ship on which passage was made.
No. 2. Port of embarkation.
No. 3. What force drives the ship?

It must be remembered that the questions under this series have nothing to do with knowledge such as is acquired through purposeful, systematic training. As will be seen the questions only intend to test the extent to which the individual has familiarized himself with the new surroundings into which he was thrown.

On first glance these questions may seem altogether too easy to throw any light on the subject at hand, but when we remember that we are dealing here with illiterates, and that whatever knowledge they have acquired was through inquiry, and due to a spontaneous sense of inquisitiveness, the questions will be seen to be quite appropriate. The criticism which might be justly offered is not concerning the nature of the questions, but rather their number. This is true of the entire experiment, but when we consider that it is not at all an uncommon occurrence at Ellis Island to have to examine five thousand immigrants in one day, and when we further remember that these examinations have to be made in practically all the known languages, it becomes at once obvious that simplicity and brevity are quite as important in this work as is thoroughness.

The results under this series were as follows:

<table>
<thead>
<tr>
<th>Question number</th>
<th>Correct answers by</th>
<th>Per cent. correct</th>
</tr>
</thead>
<tbody>

<td>45</td>
<td>90</td>
</tr>
<tr>
<td>3</td>
<td>49</td>
<td>98</td>
</tr>
</tbody>
</table>

Thus it will be seen that only seventeen of the fifty learned the name of the vessel on which they spent anywhere from seven to eleven days. This certainly, on first consideration at least, does not speak very well for the character of the present day immigration. One might justly ask are we to expect such people to familiarize themselves with our institutions and form of government, when after having spent days upon a ship they do not even know its name? This lack of intelligence, however, is only an apparent one and is due to definite psychological causes. The question of the name of the ship is quite devoid of emotional value in the mind of the average immigrant, who is making one of the most important moves of his life. The thing that is foremost in his mind is the successful passing of the gates to our country, and with many of them this idea is so predominant as to exclude everything else from consciousness.

SERIES E.

Orientation for time.

No. 1. Name of the current month. No. 2. Date. No. 3. Day of the week.

The results under this series were as follows:

<table>
<thead>
<tr>
<th>Question number</th>
<th>Correct answers by</th>
<th>Per cent. correct</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>43</td>

</tr>
</tbody>
</table>

Considering that we are dealing here with illiterates, the results in this series might be looked upon as fairly satisfactory. At any rate, the results obtained illustrate the limited value which these tests have in deciding the question of feeblemind-
edness. In the Binet-Simon scale these questions are included under the nine year old tests, while we are dealing here with individuals between the ages of eighteen and forty.

SERIES F.

Recent memory.

While the following questions are included under this heading, it is, of course, understood that it is not the faculty of memory alone which is concerned in the solution of these problems.

No. 1. Repetition of four digits.
No. 2. Repetition of five digits.
No. 3. Repetition of six digits.
No. 4. Repetition of seven digits.

The results under this series were as follows:

<table>
<thead>
<tr>
<th>Question number</th>
<th>Correct answers by</th>
<th>Per cent. correct</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>48</td>

<td>3</td>
<td>7</td>
<td>14</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>4</td>
</tr>
</tbody>
</table>

Here, above all, a comparison with the Binet-Simon scale will be illuminating. In the scale of intelligence referred to, seven digits should be repeated by a twelve year old child, if the latter is not to be considered feebleminded. Here we see seven digits were only repeated by two out of the fifty, and as has already been stated, these individuals were not feebleminded by far.

SERIES G.

Discriminative ability, and ability to perceive differences in size and form.

No. 1. Give three physical differences between a horse and an ox.

No. 2. "Healy" rack puzzle.

The first was answered by forty-four out of the fifty cases, or eighty-eight per cent, correct. The originator of the "Healy" rack puzzle, Dr. William Healy, of Chicago, director of the Psychopathic Institute of the Chicago Juvenile Court, states that it is intended to test the perspective of relationship of forms, and also the individual's method of mental procedure for the given task, particularly his ability to profit by the experience of frequent trials, in contradistinction to the peculiar repetition of impossibilities characteristic of the abnormal and feebleminded groups. The time required for solving the puzzle is given by the author as ranging between twelve seconds and two minutes. In the cases herein reported the puzzle was solved by all, the time ranging all the way from thirteen seconds to three minutes. Unfortunately no record was kept of trial and error.

Summing up the results of the foregoing experiments, we find that the thirty-eight questions submitted to fifty illiterate, male Poles, between the ages of eighteen and forty, were solved in the following manner:

<table>
<thead>
<tr>
<th>Number of questions</th>
<th>Answered by</th>
<th>Per cent. answered</th>
</tr>
</thead>
<tbody>
<tr>

<tr>
<td></td>
<td>44</td>
<td>88</td>
</tr>
</tbody>
</table>

We furthermore see that these fifty individuals who in the matter of sex, race, and educational advantages were absolutely alike, and in whom the conditions for uniform results should have been, therefore, ideal, actually showed the following wide variations in results with the thirty-eight questions asked:

<table>
<thead>
<tr>
<th>Number of persons</th>

</tbody>
</table>

The last case in the series may have been a borderline case, but a very extensive examination by another officer and myself failed to satisfy us beyond a doubt that the boy was actually feebleminded.

While, as I have already stated, I feel that no definite conclusions should be drawn from these experiments, it might not be amiss to call attention to the last table. This table shows beyond a doubt the enormous variations which exist within the limits of normality, and how dangerous any absolute and unequivocal reliance upon any rule of thumb method may become, especially in immigration work.

Here we have fifty individuals who were as near alike in most respects as is possible among human beings. Under circumstances which were as near alike as possible, these individuals were given the same thirty-eight problems for solution, and the results of correct answers varied all the way from eighteen to the full thirty-eight.

Nevertheless it is my firm belief that a set of tests could be evolved which would represent, as near as is possible, what the average immigrant of a given race should be able to accomplish mentally, if he is to be considered normal. At any rate it is the only way by which we will ever be able to solve this problem. Doctor Salmon, of the National Committee of Mental Hygiene, has amply emphasized the need of experimentation such as is herein reported in his recent work on "Immigration and the Admixture of Races in Relation to the Mental Health of the Nation," and it is sincerely hoped that the future will offer the opportunity for more extensive and thorough research into this problem.

728 West 181st Street, New York City.

GENERAL PARALYSIS IN THE NEGRO."

BY FRANCIS M. BARNES, JR., A. M., M. D.,
St. Louis,
Assistant Professor of Nervous and Mental Diseases, St. Louis University School of Medicine.

Writing in 1891, Witmer referring to the negro used the term colored race, because as he said it was probable that there were no full blooded African negroes in the United States at that time, and as a class they could not properly be spoken of as negroes for the race had become a mixed one. Although five years later Babcock criticises this position of Witmer's I believe to-day we, with more certainty and accuracy, may use the more comprehensive term colored race instead of negro, and such will be the meaning given the word negro as used in the title of this communication.

The release from bondage formed the turning point in the mental and physical welfare of the colored race. Such is the consensus, both medical and statistical. McKie, Mays, Powell, Rogers, and others all concur in the opinion that tuberculosis and insanity were extremely rare in the colored people of the Southern States prior to the Civil War, and statistics patenty show that there has been an enormous increase of both of these diseases in the colored race since the emancipation. Powell attributes this increase, in part to lack of hygienic surroundings imposed upon the freed negro primarily, and secondarily to the laxity and freedom of action which came concomitantly with emancipation from slavery. The projection of civilized vices into an un civilized class, Aryam admixture rapidly decreasing the proportion of negro ancestry tended toward a weakening of the formerly high racial resistance, and increased disproportionately the vulnerability toward constitutional diseases of every type. Hecht thinks that miscegenation with its resulting hybrid negro has been a most potent factor in the production of this lowered resistance, and we here have an excellent example of the influences of race amalgamation on the production and initiation of disease processes. Witmer, speaking of the considerable diversity of opinion with reference to the difference in types of insanity affecting white and colored people, says: "My impression is, ceteris paribus, that they are essentially the same in both," and further in the colored, "that there is no race immunity from attacks of the ordinary types of insanity, and that the manias are largely in excess of any other form," about one third of all cases. Bamister and Hektoen state that insanity, as met with in the United States African, "is especially and predominantly of the excited or maniacal type. This is what would be most naturally expected judging from the general characteristics of the Southern negro." Da Rocha, studying Brazilian mulattoes, and Babcock, working with the American type of negro, likewise found mania very common.

If we now narrow our scope and fix our attention, upon the occurrence of a single type of mental disease, general paralysis, in the colored race, we find at first that the increase in mental disorder as a whole in this race since the war applies equally well to paresis. Babcock writes that Roberts of North Carolina in 1883 had never seen a case of general paralysis among his colored patients, nor had Powell of Georgia in 1886 in a "full blooded negro." Witmer found thirty-eight paretics among nine hundred and six colored patients admitted under his care between 1855 and 1886, a period of thirty-four years. Of eight hundred and four patients admitted to the hospital within the past five years, seventy-four were paretics. These figures show obviously the increase in total admissions of colored insane to the hospital as well as the disproportionate increase in the number of paretics. The common belief, as stated by Chase, was to the effect that paresis was long supposed to be confined to the Anglo Saxon race, and Hecht finds that takes almost exempts the negro. Burr states that paresis is rapidly becoming as common in negroes who have an admixture of white blood as it is in Caucasians, though in real negroes it is almost unknown. This same writer offers the generalization that the gross syphilitic diseases of the nervous system, which are primarily vascular and not nervous disorders, are common in negroes while the paralytic diseases are very rare. The effect of change of environment upon the resistance of the colored race to paresis is recognized by Chase as follows: "It is said the disease was unknown among the slaves of the Southern States and unreported among free negroes until they came to the centres of population. At present (1902) in Baltimore, as an instance, paresis claims the same percentage of negroes according to the population, that it does among the Caucasians." Also, Kiernan makes this same point when he says: "The increased percentage of paretic dementia among negroes is due to the fact that the negro in Chicago (1886) is treated as an equal in commerce and politics, and is thoroughly under the influence of the speculative atmosphere which permeates the commerce of the city." Kiernan found that nine per cent. of his cases were paretics, while in New York, Spitzka (cited from Chase) found 8.9 per cent. among the colored insane. Kraepelin states that the North American negro is relatively more prone to the disease than the whites, and on the basis of figures obtained from seven large North American insane hospitals, he shows that the average incidence rate for paresis was 11.2 per cent. for men, and 7.8 per cent. for women. Da Rocha, in Brazil, on the contrary, finds paresis very seldom among the colored, no case occurring in the series of fifty-seven colored insane studied by him. Finally, Bannister and Hektoen conclude "that general paralysis is not a disorder to which any race is immune, but one that depends upon causes independent of racial or national peculiarities."

Witmer's impression that the types of insanity affecting the white and colored people were essentially the same in both has been previously quoted. I believe however, that this is only partially true, and in a previous paper I have pointed out that among paretics the colored suffer from hallucinations more than twice as frequently as the whites. Kiernan recognizes this when in speaking of the credulity, belief in Voodooism, etc., in the negro, he says: "The psychic peculiarities dormant in the race crop out very prominently in these (paretic) cases, and it would appear certain from these that the
question about the influence of the superstitions of the race must be answered in the affirmative."

Numerous papers dealing with statistical data relative to paroxysm in the white have been written, but I have been unable to meet with any similar work done on colored paroxysm. My attention was first directed to this subject while studying the occurrence of hallucinations in paroxysm. As has been mentioned, in that study it was found that colored patients suffering from paroxysm gave evidence of hallucinatory disturbances more frequent as did the whites—39.6 per cent. in the former, and 17.3 per cent. in the latter. This was to a degree unsatisfactorily explained by the recognition of a fundamental difference in mental development in the negro as compared with the white race. It was assumed that in the stage of development the colored race occupies a lower level, is nearer, it may be said, the perceptual life of a primitive people. Therefore, on this assumption, when disease disrupts acquired characteristics, one might expect a ready return to this lower level with its more primitive tendencies.

Having noted this striking difference in one symptomatological phase, the question immediately arose as to whether the colored paroxysm differed in other respects from the white. To determine if such might be the case, the records of all patients under observation during the period of five years ending March 31, 1913, when a diagnosis of paroxysm was made, were gone over and so far as the material available was satisfactory, the important points have been statistically studied. As a basis of comparison with the white race, the excellent work of Junius and Arndt, which deals in a thorough and most comprehensive manner with paroxysm statistics, has been chosen.

During the five years period covered by this study there were admitted

This table shows that the most frequent age of admission, and this may be taken also with slight modification as the age of onset, is between thirty-six and forty years in males, and thirty-one and thirty-five years in females. This agrees very closely with the figures of Junius and Arndt, those for 58.6 per cent. of the male and 21.9 per cent. of the female paroxysm between the ages of thirty-six and forty.

</table>
In about half (twenty-six) the duration on admission had been eight months or less; in fifteen, from eleven to thirty months, and in seventeen unknown. This would bring the average about one year, the figures usually given (Junius and Arndt, Guddin, Ascher, Heilbronn). Junius and Arndt found that the average time under treatment was for men nine and one third months, and for women, ten months. Heilbronn and Ascher (cited by Junius and Arndt) give about fifteen months as the duration of treatment for males, and this would nearer correspond with my figures.

As to nativity, all were born in the United States, fifteen in the District of Columbia, seventeen in Virginia; seven each in Maryland and unknown States, three each from North Carolina and Tennessee, one each from Alabama, Arkansas, Georgia, Indiana, South Carolina, and Texas. As might be expected, more than half came from the District of Columbia or bordering States. Some of those having come from more distant parts of the country have been admitted through military or penal channels. In this connection we find that males were admitted from some branch of the military service and, as is usually found, all of these had given a number of years of valuable service, ranging from five to twenty-three. Among these were two noncommissioned officers. Regarding criminal record in paralytics, we find among these cases the usual run of affairs. None of the females had a criminal record, while six males had come within the purview of the courts for criminal acts. One of these only had made a homicidal attack, and this act was committed at a period considerably antedating the appearance of any symptoms of the paretic mental disorder, there being in the record no reason to suppose that his diseased mental state had any connection with, or bearing upon, the criminal act. Among the five others, there was not an habitual criminal, in each instance the infraction of the law had been of the nature of some petty larceny of misdemeanor, very obviously resultant upon the mental disease.

As to religion, education, and occupation, we find nothing unusual for the people of the colored race. Twenty-eight were of the Baptist faith, four Catholic, seven Methodist, eight Protestant unspecified, the remainder unknown. In twenty the education is given as good, meaning thereby the customary common and grade school advantages; in twenty-two as poor; in twelve, none, and in four, unknown. Thirty-five of the males were laborers, the remaining number being distributed among barbers, butchers, waiters, undertakers, clerks, etc. Of the females, all were cooks or domestics. As to the civil condition, twenty-three were given as single, one unknown, and the remainder married (widowed or divorced).

Relative to the predisposing etiological factors, the greater number of the case records offers uncertain information. Among the antecedents, nervous and mental diseases were noted in twelve cases, alcohol in twelve, tuberculosis in twelve, syphilis in one (the juvenile case). In the personal history there was found a record of alcoholism in twenty-nine cases, syphilis in twenty, head trauma in six, and tuberculosis in four. The records show that only one of the noted cases had been excessively alcoholic prior to the beginning of the present mental disease, and it seems more probable that in the others we have the alcohol predominating as a symptomatic rather than a causal factor. It must be borne in mind that obtaining accurate anamneses from colored patients is as a rule quite impossible, and a truer history might show more evident alcoholism. In no case where the head trauma is noted does it seem to have been of great importance, certainly not more than a necessary cause. This is in accord with the generally expressed opinion that trauma as a prime factor in the etiology of paresis is very unusual. In one case the trauma, received many years before the development of paresis, supposedly resulted in a traumatic epilepsy.

In fifty per cent. of the cases seizural attacks of various types occurred. In forty-nine patients the general physical health on admission for treatment was good, in the remainder poor. Speech disorders incident to the disease were noted in fifty-six cases as present, and in one as absent.

The ocular signs of disease were found present or absent as follows:

<table>
<thead>
<tr>
<th></th>

In more than half (sixty-three per cent.) of the cases some abnormality of the ocular apparatus was demonstrable, these figures being much lower than those given by Junius and Arndt.

Tendon reflexes were not recorded with sufficient detail to make satisfactory study possible. On this account, as with the eyes, no attempt has been made to determine whether one or both sides were affected equally, if at all, or to what extent.

Junius and Arndt found the patellar reflex increased in fifty-four per cent. of their cases and from weak to absent in 29.6 per cent. The data at hand are sufficient to permit of any comparative computation with the cases under consideration.

The cytoscopic findings in the blood and cerebrospinal fluid, where an examination had been performed, were in every case record positively indicative of paresis, according to our present conceptions of the diagnostic value of these laboratory examinations. Although a history of syphilis in the patient was obtained in only twenty cases a positive Wassermann reaction with the blood serum was obtained in forty cases, and with the cerebrospinal fluids in thirty-four. The Noguchi protein test was positive in the spinal fluid of forty-three patients. The cell count of the latter fluid ranged from fourteen to four hundred and fifty-one in the males, and from thirty to one hundred and thirty in the fe-
males, an average of one hundred and nine in the former and seventy-two in the latter. (In forty-one cases counts were made.)

The onset and course of the disease show nothing unusually striking by way of difference from that noted in the Caucasian. In thirteen the onset was sudden, in thirty-four, gradual. In some of the thirteen suddenly onsetting cases, a seizure was the first recognized manifestation of the disease. The course might be characterized as gradual in thirty-six cases, rapid in twenty. In fifty the disease process progressed without noted interruptions, being of the characteristically progressive type. Definite remissions occurred in eight instances, about thirteen per cent. Of the fifty-eight cases, forty-five died, three were discharged to relatives or other institutions, and ten remain under observation. In forty-one cases autopsy was performed and the diagnosis of paresis confirmed.

By some it is believed that the demential type of paresis is more commonly met with in the colored race than in the white. The grouping of the cases according to types has been made here although it is fully recognized that this division is of little interest or value, the writer agreeing with Binswanger that we cannot divide paralytics into these separate types as such classification is more or less arbitrary and dependent largely upon the stage of the disease process during which the patient is observed.

Type of disease. Male. Female. Total.

Demential 31 9 40
Expansive 5 1 6
Depressive 1 1 2
Agitated 7 .. 7
Mixed 1 .. 1
Juvenile 1 .. 1

Sixty-nine per cent. of these cases are classed as of the demential type, being almost twice the number found by Junius and Arndt among whites. It is apparent that there is some justification in the belief in the frequency of the occurrence of the demential type among the colored paralytics.

Other elements of the symptomatology which might be mentioned are the delusions and hallucinations. Twenty-four males and five females exhibited delusions of one or more types, i.e., fifty per cent. of all cases. The statement of Kiernan, that the superstitious traits of the negro character flourish preeminently in the colored paralytics, does not appear to be particularly well borne out by these delusional cases. It is true that the delusions of an expansive character are possibly more absurd and exhibit a greater lack of critic than in the white, as a rule, but this can as well be due to the low grade of educational advancement attained, as to a fundamental characterological anomaly of the race. Whites, with as meagre an education, as frequently show a similarly low grade of critical power. Another explanatory feature may perhaps be found in the fact, that a larger portion of colored paralytics are to be found of the demential type. In a few isolated instances the delusions were of an alcoplastic nature, and found expression in mystic form, as persecution by witches, evil spirits, the devil, etc. These instances are not, however, met with in sufficient frequency to permit of a characteristic or particular coloring of the delusional ideation of the negro paretic. They are met with as frequently, and indeed more often, in the colored precox. The delusions in other respects do not differ essentially from those met with in the white paretic.

Mention has already been made of the dispropor-
tionate frequency of the occurrence of hallucinations in the colored as opposed to the white paretic, fallacious sensory perceptual disturbances being present in the former with twice the frequency demonstrable in the latter. Auditory hallucinations are by far the more frequent, those of other senses either occurring alone or in association with another are to be noted. Of the fifty-eight patients twenty-three, eighteen males and five females, showed hallucinations of one or more senses. Alcoholism appears to have played no important rôle in their occurrence. The hallucinatory content is, in the colored, of a more elementary character, and especially is this so of the auditory hallucinations. In this sensorial realm, more than in the delusional, we find a more evident justification of Kiernan’s remarks concerning the racial characteristics, as they may find expression in the colored person whose brain is the seat of the paretic destructive process. Voices of the devil’s emissaries, mysterious messages of spiritual origin, sometimes of a pleasant, laudatory character, again of a fearful, terrifying content, as a rule the content harmonizing fairly closely with the prevailing emotional tone of the patient, are no doubt more frequently exhibited by the colored paretic than by the white when afflicted with the same disease, and very plausibly may be taken as evidence of the outcropping of a characteristically primitive racial credulity, and absence of full adaptation to advances in the present day intellectual—civilization.

Of previous attacks of a mental disorder there are four instances recorded. One of traumatic epilepsy, one of alcoholic psychosis (delirium tremens?), one of feeblemindedness (a juvenile case), and one of hysteria (?), the attack having antedated the present illness by five years. One patient had a hemiplegia of several years’ duration.

RÉSUMÉ.

The term negro as applied to the United States African less accurately designates this class of people than colored race, the latter term being the more comprehensive and at the same time conveying the added meaning of the racial admixture. This hybridization of the race by miscegenation and amalgamation may be taken as the explanation for the fact, that general paralysis, a disease in which the full blooded negro was practically immune a half century ago, has not only become prevalent among this people, but even occurs with greater frequency than in the whites living in a similar environment.

Taking into consideration the short life of this mixed race, it might be anticipated that there might be found, in a given disease such as paresis, certain symptoms which arose more or less from the original racial subsoil, and that this characterological influence might lead to a modification of the symptomatology of paresis as observed in the white. Such anticipation is in part justified in
several respects, most notably in the greater frequency of the occurrence of hallucinations, the predominance of the demential type of the disease, and the greater frequency of paresis among colored females than among the whites of the same sex.

Twenty-three and six tenths per cent. of all patients admitted during the past five years were colored; 9.2 per cent. of these were paretics, while 7.4 per cent. of the whites admitted were paretics. Paresis is more frequent among the colored race as a whole than the white, and nearly three times as frequent in the colored female as in the white. Fifty per cent. of the cases of paresis were admitted between the ages of thirty and forty years.

In about fifty per cent. the duration of the disease on admission was eight months or less, the balance having been in existence for a longer period, bringing the general average duration prior to the beginning of hospital treatment up to about one year plus, the period usually given for whites. In fifty-eight per cent. of the cases the onset was gradual and in sixty-two per cent. the usual gradual progressive course was followed. Definite remissions in the course of the disease occurred in thirteen per cent. of the cases.

Hereditary taint such as alcoholism, nervous or mental diseases, syphilis, tuberculosis, etc., was noted in about twenty per cent., but in only one instance, a case of juvenile paresis, was it possible to prove a similar heredity. Fifty per cent. of the patients were alcoholic, but only one excessively so, and it is believed that the alcohol in these cases is more symptomatic than causal. Head trauma was noted in only six instances, and in none could a definite connection be made between it and the paresis be established. Previous attacks of mental disorder in colored paretics are rare, having occurred in this series in but four patients, and in no instance was the attack similar to the symptoms manifested by the patient as a paretic.

Those colored males admitted through military channels, as is likewise customary with white paretics from similar sources, had records of good and faithful service rendered over a prolonged period of years, and some had been promoted to higher grades upon the basis of examinations or meritorious service. Criminality among the paretics was in these cases, as is the rule, rare and, excepting for one instance, was of the occasional type, and the crime itself evidently dependent upon the disease for its commission.

Religion, education, and occupation show nothing unusual for the race under consideration and no bearing upon the question of paresis could be ascertained. The recorded civil status likewise offers nothing of especial interest.

The frequency of the demential type of paresis among the colored race has been commented upon, this type comprising sixty-nine per cent. of the patients examined. In about fifty per cent. of the cases, seizures of one type or another occurred. Anisocoria was present in forty-four per cent.; pupillary irregularity in fifteen per cent.; the direct light reaction was absent in fifty-eight per cent., and the consensual light reaction was absent in sixty-three per cent. of the cases. Quantitative description of the tendon reflexes is impossible because of inadequate notation of examination and that the knee jerks were present in seventy-two per cent. of the cases is the only statement which seems warranted. The cytoscopic examinations made of the blood and cerebrospinal fluid were positively indicative of paresis in all cases so examined. About fifty per cent. of the patients entertained delusions of one or more types, and thirty-nine per cent. were, at some period, generally early in the disease, hallucinated in one or more senses, their occurrence being noted with more than twice the frequency with which they are observed in the white paretic (17.3 per cent.). The hallucinations in the colored paretic tend to assume a mystic character, which more or less accords with the primitive intellect of the colored race. This trend cannot, however, be looked upon as in any way characteristic of the paretic, similar trends being observed as frequently, and in as pronounced form, in other forms of mental disorder, as observed in the colored race.

REPORT OF A CASE OF RETROPHARYNGEAL ABSCES IN AN ADULT.

By C. M. MANN, M.D.,

New York.

Visiting Physician to St. Josep's Hospital for Tuberculosis.

Noticing the statement of the infrequency of retropharyngeal abscess in the adult by Doctor Alexander and Doctor Montague, appearing in a recent issue of the New York Medical Journal, it occurred to me that a brief report of such a case might not be without some slight interest.

The patient in question, a superintendent in an apartment house, living in the basement, thirty-three years old, and married, came to my office with a history of having been healthy since childhood, except for attacks of acute articular rheumatism coming with some regularity in the spring and fall. Occasionally the attack would fail to develop at the expected time, "throat trouble" taking its place invariably. He had felt ill for three days past—having a painful cough, fever, and several chills, followed by sweating. He also complained of severe pain in the back of the throat, with a sense of fulness, making swallowing nearly impossible. He had, however, kept at his
employment in a desultory fashion. On examination his temperature was 103.4° F.; pulse, 106; respiration, 20. His heart and lungs were normal. Tongue badly coated, teeth decayed. A mass, fluctuating in the centre and very tender, projected from the left posterior pharyngeal wall. The tonsils were both slightly swollen and the whole pharynx reddened and tender. As the patient refused incision he was put to bed. Aspirin, ten grains every four hours, with astrigent gargles and ice bag to neck being ordered. The swelling was also painted twice a day with tincture of iodine. On the second day spontaneous rupture occurred, the patient spitting out considerable pus, probably two or three tablespoonfuls. A rapid fall in temperature and an uninterrupted recovery followed.

A NEW METHOD OF DIAGNOSTICATING MASTURBATION IN GIRLS.

By Bernardo Kaufman, M.D.,
Marysville, Cal.

The role that masturbation plays in the diseases of childhood seems to have been lost sight of, for I am sure that some of the more common conditions seen by the general practitioner are due almost entirely to this habit, and with the checking of the practice the conditions will clear up.

J. P. West reported a case of an infant six months old who was supposedly suffering from epilepsy, but who was exhibiting the effects of masturbation, and in whom everything cleared up when the correct diagnosis was made and provision made to prevent its continuance.

Such a case has come under my notice and the method of diagnosis being, I think, original and at the same time simple and easy of application, I deem it worthy of publication.

Masturbation is practised with the finger or with some foreign object of one sort or another. Digital masturbation consists ordinarily in little girls in friction of the clitoris and of the inner surface of the labia; there is nothing in these manipulations that can injure the hymen.

Hofman has, furthermore, examined with this object in view idiotic and imbecile girls of all ages, such as abandon themselves to masturbation passionately, as we know; he has never seen ruptures or traumatic lesions of the hymen.

According to Havelock Ellis it is impossible to diagnosticate masturbation by the size of the clitoris, and yet, according to Freud, masturbation is directed almost entirely toward the clitoris in very young girls.

This shows the close relation, during the act, of the fingers to the urethral orifice, and this accounts for the readiness and ease with which the diagnosis can be made. It also shows that while a critical examination of the hymen might seem to be of value, yet in practice it is left alone and remains intact.

As to its frequency, we have no accurate means of telling, but it must be very common. "Among women of a good class, there are some indications that it is by no means uncommon, as for instance, where one thousand consecutive gynecological cases showed well marked vulvar hypertrophies in over one third. By one third of the third, full admission was made, so that it is fair to attribute the findings in the remainder to the same cause especially as categorical denial was forthcoming in only one in fifty."

This being the case with reference to "women of a good class," what can we expect with young children, who have no ability to judge of the propriety of the act.

Among younger children, the proportion who masturbate is also very high. According to Berger ninety-nine per cent, of young men and women give themselves up to this practice. Debreyne quotes a cure, in France, that among the little girls who came for their first communion, eleven out of twelve were given to masturbation.

Now that some idea of its prevalence has been shown, how can we prove it in doubtful cases? Kelly gives minute details for the diagnosis in women after it has continued over fairly lengthy periods. But how about young children who have just started to practice manipulation. The method I use is as follows: First take a specimen of urine and examine it microscopically to determine the absence of yeast. Have the mother prepare some yeast and make the child play with it at night time just before it is put to bed. It is better to have the yeast fairly moist at first, as it then cakes on the hands better. Then, without allowing the child to wash its hands, put her to bed, using a shortened nightgown. Next morning, have a thoroughly cleansed vessel for the child to urinate into, and bring the specimen to the physician's office. This is centrifuged, and on putting the sediment under the microscope, the yeast can be readily recognized. The presence of the yeast fungus is proof positive of the practice of masturbation.

The following case is of interest, as it was from the microscopic findings in this case, and the deductions following these findings that not only solved this case, but led to this method of diagnosis.

CASE I. E. C., aged seven years, was brought by her mother to my office. The mother had noticed the child was not well, but although she had watched her closely, she could detect nothing definitely wrong with her. She had lost five pounds within four months, had no appetite, did not sleep well, awoke every morning about 4 a.m., and from that time on dragged herself about the house, always listless and restless and not playing with the other children.

Examination revealed nothing abnormal. Blood normal; no malarial parasites; hemoglobin normal. Urine contained no albumin and no sugar; microscopically, showed an abundance of yeast present.

On questioning the mother whether she made her own bread, I received an affirmative answer, and on further questioning, I learned that the girl was in the habit of playing around the table at such times. I then came to the conclusion that this was the source of the yeast and that the child carried some of it still on her hand when manipulating herself, which was afterward to be found in the urine.

On announcing my diagnosis to the mother, she became indignant and left my office, but returned in four days to tell me that she had observed the child in the act.

Suitable precautions were then instituted, and as the
child was old enough to be lectured, the evils and dangers incidental to this habit were vividly portrayed to her, and the child made to thoroughly understand the dangers she was running. The result was a complete change in the child; all the peculiarities which the mother had noted were gradually lost, the girl grew stronger and was apparently well again. Several tests by this method have since been negative.

H. A., aged nine years. Female. I was sent for early one morning about thirty months ago and on arriving at the home found the child as though recovering from an epileptic attack. The following history was given:
The child awoke apparently as usual and called from her bed to her mother saying she did not feel well. Her mother could reach her, she let forth a scream and began convulsive movements of the whole body. These persisted about fifteen minutes and then subsided, the child going to sleep and awakening in about half an hour drowsy and stupid. These attacks occurred from time to time at intervals of three or four months, and were always of the same type. The family history on both maternal and paternal sides was negative, both parents denying any nervous ailments in any member of either family. There were five other children of the same parents, two boys and three girls, all living and well and none of them at any time had shown any symptoms of nervous derangement. This girl was the second youngest; the mother's pregnancy was normal with an easy delivery. During infancy the child was free from any serious ailment; likewise free from spasms. She had had measles and chicken pox, both mild attacks, and made apparently perfect recoveries in both illnesses. Aside from these, there had been no sickness.

Physical examination showed an apparently healthy child, well built and well nourished with no organic lesions. The urine was normal in every respect. Suspecting masturbation to be the cause of her troubles, I suggested to the mother the advisability of applying the test as a means of finding out if she indulged in this practice. The mother consented and the details were explained to her. Her urine was examined every day under the microscope for two weeks, but in no instance was any yeast found. To make sure there was nothing wrong in the procedure as far as the test was concerned, I had the mother go over the method she employed. I found that the child after playing with the yeast was allowed to wash her hands before retiring. This was stopped. In the next morning's urine yeast was present in great quantities. The child was brought to my office and thoroughly frightened. This was eight months ago. The test had been repeated with negative results, and the attacks also had ceased.

CONCLUSIONS.
This method of diagnosis is not offered as absolutely infallible, but at least it is prima facie evidence (of the fact) that the child was handling herself at that time. Whether it was a coincidence, that at that particular time there was a local irritation that caused the child to put her yeast laden hands there, can only be determined in a long series of cases, but at least in these and other cases in my practice, it has served a definite purpose and helped in clearing the diagnosis in obscure cases and eliminating this habit as a factor in other cases. It is in this spirit that it is offered as a help to the busy general practitioner.

**Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:**

CXXXVII.—How do you treat insomnia? (Closed September 15th.)

CXXXIX.—How do you treat chancreoids? (Answers due not later than October 15th.)

CXL.—How do you treat the symptoms of senility, without organic disease, but showing approaching dissolution? (Answers due not later than November 15th.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisors will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the *Journal*. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXVII was awarded to Dr. W. C. Hess, of Cresco, Iowa, whose article appeared on page 763.

**PRIZE QUESTION CXXXVII.**

THE TREATMENT OF THREATENED ABORTION.

(Concluded from page 723.)

Dr. Alfred Costales, of Brooklyn, N. Y., holds that:

When called to attend a case of threatened abortion, after satisfying ourselves that the patient is really pregnant, as ascertained by the history obtained, and by a very careful and complete physical examination, at the same time noting the probable duration of gestation—we order the patient to keep in bed, keep her in the recumbent position, and proceed as follows: Washing and scrubbing the hands and arms with soap and hot water, carefully disinfecting the same with bichloride solution, one in 2,000, or alcohol full strength, touching the hands, and then the whole hand thoroughly with some antiseptic lubricant, we make a vaginal examination and feel the condition of the os uteri and cervix. If the os is found undilated and the cervical canal unexpanded, the hemorrhage being slight and the pains controllable, we have to deal with a threatened abortion and recommend absolute rest in bed, forbidding all excitement, etc. The indications are to arrest the further progress of the case by giving the patient a hypodermic injection of morphine, ½ grain, and atropine, 1/150 grain; or pulvis opii, ½ grain, and gallic acid, three grains, every three hours, for a few doses only, to arrest hemorrhage and pain; or one drachm of the compound tincture of viburnum opulus (National Formulary) every two or three hours. In the majority of the cases we will not succeed because the patients will not carry out our orders, as in the present epoch they prefer to get rid of it.
If the case becomes one of unavoidable abortion, as indicated by a dilated os, profuse hemorrhage accompanied by sharp uterine pains, and the os and cervix are dilated enough to admit one or two fingers, we at once proceed to evacuate the uterine cavity by peeling off the membranes and removing the entire uterine contents. Making downward counter pressure on the uterus through the brim of the pelvis, with the other disengaged hand, so that it will be helpful in our manipulations; or we can introduce an irrigating curette properly sterilized, and remove all rough surfaces found therein, by gently curetting and using at the same time a hot intrauterine bichloride douche, one in 5,000, at about 115° F., or using the tincture of iodine, one drachm, to the quart of hot water. If necessary, we may bring down the uterus with a forceps or a tenaculum, thus facilitating our purpose. Give the patient one drachm of fluid extract of ergot, every three hours, for a few doses. If the os and cervix are not dilated, we must have recourse to dilatation by mechanical means, as follows: After introducing a large vaginal speculum and locating the os and cervix, we insert Hagar dilators in succession, or use any good cervical dilator and gradually dilate the canal until it is large enough to admit of packing, say one quarter of an inch or more. We then pack the cervix and vagina with long strips of iodine or other antiseptic gauze or, if preferred, we may insert, to advantage, a medium or a large sponge or tupelo tent, which will have the necessary effect of arresting the hemorrhage, however severe, and in from four to six hours we will find either the fetus expelled into the vagina, or the cervical canal so pervious that operative measures are at once available, either with the fingers (always to be preferred) or with the curette. A correct procedure in these cases, where hemorrhage is alarming and the cervix undilated or nearly so, would be to call an assistant, anesthetize the patient, and proceed at once by manual dilatation to evacuate the womb, using an abundance of sterilized lubricant for the hands, which will greatly facilitate the operation; never forgetting to use the hot antiseptic douche of bichloride, or the tincture of iodine, as mentioned, and, if need be, a hypodermic injection of ergotin, thus:

R. Ergotini, ...........................3½; 
Aque destillatae, .......................5iij.
M. Sig.: Sixteen minims for hypodermic injection in buttocks, every three hours until effectual.

Or the following:

R. Cotarnina hydrochloridi, ....................grs. 1; 
Ergotini, .............................grs. ½; 
Aque destillatae, .......................5iij; 
Strychnine sulphatis, ..........................gr. 1/50.
M. Fiat capsula No. 1. Tales doses No. xii. One every three hours.

Or pituitrin may be given hypodermatically.

Dr. M. Auslander, of New York, observes that:

Treatment should be directed to overcome the tendency to abort, and later to avert a recurrence. The immediate treatment for a single case is about as follows: The patient is placed in a room alone to insure quiet for mind and body. She should receive a sponge bath of luke warm water and soap followed by a water and alcohol rub, and then be thoroughly dried and placed on a level bed and ordered to remain flat on her back. A suppository containing one grain of extract of opium is given morning and night and one drachm of fluidextract of viburnum prunifolium three times daily. Her diet should be very light. Milk and two slices of buttered toast for breakfast, a plateful of chicken bouillon for dinner with bread, butter, and a baked apple. Milk, a soft boiled egg, and bread and butter for supper. Carbonated water in moderation may be given as a drink. Her bowels should move at least once in two days. If the bowels are not sufficiently active, two drachms of fluidextract of cascara may be given every twelve hours. Three grains of chloral and five grains of strontium bromide may be given in conjunction with one grain of extract of opium or eight minims of laudanum by the mouth every four hours. If under this treatment for several days bleeding and cramps show no tendency to subside then it will most likely continue and become, what is called, an inevitable abortion. Whereas, if the symptoms show a tendency to abate then treatment should be continued. When the symptoms have disappeared the patient should be allowed a gradual increase in diet, and more liberty to roll about in bed, or to sit up, as soon as the bleeding stops. A day or two after she is permitted to get out of the bed, and gradually resume her duties.

When the patient has recovered from the present attack we must look for the underlying causes that have brought it about. These are as previously stated of a general or local nature. In general illnesses, as contagions of infectious diseases, poisons accumulate in the maternal blood and these excite uterine contractions. Treatment is directed more for the cure of the patient than to prevent abortion. In phthisis and luetic infection no effort should be made to avert a threatened abortion. In blood disorders or pernicious anemia accompanying threatened abortion, after the patient has been tided over her present attack she should receive arsenic and iron and a nourishing diet. In asthma and incontrollable coughing, rest in bed with sedatives are advocated and, if possible, a change of air. Nervous disorders as chorea, hysteria, and epilepsy, cause spasmodic muscular contractions and may affect the uterine muscle. Here again treatment consists of sedatives and rest. Of local conditions we must consider irritable uterus and displaced uterus. Here again we give sedatives and avoid excitement and if possible correct any displacement. Persistent vomiting may bring on a tendency to abortion because of the constant muscular contractions. If sedatives and rest do not stop the vomiting then it were best to allow no interruption of the abortion.

Dr. Edward Swift, of Los Angeles, Cal., emphasises the fact that:

The cardinal feature in the treatment of threatened abortion is rest in the recumbent position. This is essentially the first element of treatment and should be insisted upon. The next thing in order is a careful bimanual examination of the patient to determine the degree of dilation of the cer-
vix—if such exists—and thus settle the question definitely as to whether or not expectant treatment should be undertaken as preferable to the more radical treatment of dilatation and curettage.

Packing the vagina with sterile gauze is unquestionably of value, but in carrying out this procedure care should be taken to pack the anterior and posterior fornices. The packing should be removed in twenty-four hours and then replaced if the bleeding continues. Packing in this manner holds up the uterus and by thus relieving the congestion decreases the amount of bleeding.

Uterine sedatives have a place here, particularly in those cases where the uterus has a tendency to cramplike contractions. Fluidextract of hydrastis, in doses of twenty minims, given in a little water, every three hours, or fluidextract of viburnum, given every three hours in doses of one drachm in water, usually have the desired effect. If the pain is severe one half grain of codeine sulphate, by hypodermic injection, will be found serviceable. Morphine, though used by many, seems to have a tendency to prolong the nausea if not to increase it. Where nausea and vomiting are not present morphine in dose of one fourth grain may be used with good results but should rarely be repeated.

The treatment of the cause is naturally the only course to pursue. When due to constitutional conditions such as syphilis, tuberculosis, chronic nephritis, or cardiac lesions, expectant treatment is of little avail. Though it may relieve the condition and alleviate the symptoms temporarily, inevitable abortion usually supervenes, and then curettage is the method of choice.

Those cases which are most amenable to treatment are due in a large majority to a toxemia. This must be recognized and should be sought for in every instance. The leading symptoms, aside from those of the threatened abortion itself, are: Headache, vomiting, high tension pulse, and pain in the pit of the stomach. A careful examination of the urine will reveal the presence of acetone and diacetic acid, together with an increase in the amount of indican. Albumin is a rare constituent of the urine in these early cases. Acetone is often present without the presence of diacetic acid, but when the latter does appear it denotes a more severe degree of toxemia. Tests for these substances should not be overlooked but they should constitute part of the routine examination of the urine throughout pregnancy. In the cases due to this early toxemia the treatment essentially resolves itself into that of an acidosis. Free elimination, careful diet, plus large doses of sodium bicarbonate is the treatment indicated.

From the diet all raw fruits, meat, and eggs should be eliminated. Broths, soups, zwieback, and buttermilk should be the extent of the feeding for the first few days. As improvement takes place the patient may be allowed fish (if this can be obtained fresh), baked apple, apple sauce, baked potato, and finally a little white meat of chicken. Gradually as improvement takes place, as indicated by the clinical symptoms and the amount of toxic substances in the urine, the diet may be increased until the patient is again enjoying her accustomed dietary.

For the treatment of the nausea and vomiting cerium oxalate in ten grain doses given in a little milk every two or three hours will be found efficacious. This may be augmented by the administration of choral hydrate in doses of fifteen grains each, combined with thirty grains of sodium bromide, given by the rectum, night and morning.

To increase the elimination one bottle of citrate of magnesia, or one ounce of epsom salts, may be given every morning. The first dose of saline may or may not be preceded by two and one half grains of calomel, given in doses of one half grain every twenty minutes for five doses.

For the acidosis thirty grains of sodium bicarbonate, every three hours, should be given. The urine should be examined every day and, as the acetone or diacetic acid or both decrease, the amount of the sodium bicarbonate may be gradually lessened.

In some cases the injection of glucose (one drachm to the pint of water) has proved serviceable in overcoming the toxemia. This injection should be given by the rectum by the Murphy drop method.

Dr. Herbert K. Thoms, of New London, Conn., believes that:

Hospital treatment is of great value, and even the small country hospital has many advantages over the modern home, for we must be ready to treat any of the more severe complications which may supervene. The matter of moving these patients must be left to the judgment of the physician.

The first essential is rest in bed away from the influence of friends and relatives. Every form of mental excitement must be eliminated as well as the characteristic pain. For this purpose one fourth grain of morphine should be given at once, hypodermatically. The two chief symptoms are pain and hemorrhage. Having secured absolute freedom from pain, our next step is to determine as far as possible the source of the hemorrhage. A careful bimanual examination may reveal a placenta prævia, a ruptured bag of waters, or even a foreign body, such as a bougie or catheter.

If the pain is under control and the flow is not severe, our treatment is an expectant one. Good nursing and vigilant watching are of paramount importance. Whether pain recurs or not, it is advisable to keep the patient as quiet as possible, and a rectal suppository containing one grain of extract of opium should be used every four to six hours. In mild cases or at any later period a suppository of codeine combined with extract of hyoscynamus and extract of viburnum pruni folium may be substituted.

In regard to diet, a restricted, nonstimulating, fluid diet should be instituted at first, which of course may be changed as the case progresses. The bowels should be kept freely opened, especially at first. This should be accomplished by enemas in order to avoid any straining.

The amount of blood lost should be carefully
noted. If the amount does not exceed that of an ordinary menstrual flow, we may continue our expectant treatment. However, if the flow exceeds this, and if the patient shows signs of anemia, the uterus should be emptied by appropriate means. In the majority of cases the treatment as outlined suffices.

In some cases, however, the hemorrhage persists, to some degree, for one or even several weeks. In these cases the question of the viability of the fetus must be answered. This can only be done by waiting two or three weeks and then at a reexamination determine whether or not there has been the proper enlargement of the uterus. In the absence of such enlargement and of the other usual signs we may be sure that the fetus is dead, and the uterus should be emptied under aseptic conditions. We must bear in mind that in this instance abortion will inevitably occur sooner or later and the immediate emptying of the uterus secures less chance of infection. After all pain and hemorrhage have ceased we should insist that the patient shall remain in bed for at least a week. Following such an attack the patient should be carefully instructed as to a careful mode of living to avoid any further trouble.

Dr. M. L. Curtner, of Vincennes, Ind., states that:

If the threatened abortion is due to a dead fetus in utero, evacuation of the uterus should take place immediately.

In threatened abortion due to any other cause, the cause should be ascertained and removed if still existing (such as hair pins, lead pencils, or catheters within the uterus).

The direct expulsion of the fetus is due to uterine contraction and the treatment of threatened abortion is directed at the uterus to abolish its muscular activity. The rational procedure for this end is complete rest in bed, with an ice cap over the pubic region and morphine hypodermically, in sufficient doses to entirely relieve the uterine cramps.

The patient should not be permitted out of bed until the uterine cramps have completely subsided.

Unless the bowels move of their own accord after the administration of the morphine, a soap-suds enema should be used for this purpose. Following this a mild laxative may be given if necessary.

Therapeutic Notes.

Treatment of Puerperal Endometritis.—P. Delmas, in Presse médicale for June 7, 1913, is credited with strongly advising the use of tampons soaked in oil of turpentine in puerperal endometritis. After exposure of the cervix by means of a speculum, a strip of gauze varying in length according to whether the uterus is abortive or puerperal, is dipped in the turpentine and inserted systematically with long forceps into the uterine cavity. One end of the strip is left in the vagina, from the walls of which, previously irrigated with boiled water, it is kept separated by a tampon of cotton. All burning of the vulva is avoided if the parts are first piously covered with petrolatum. The intrauterine strip is removed only after twenty-four hours.

In a first series of cases, the author used the turpentine where, with retained membranes, digital or instrumental evacuation of the uterus, followed by iodine, failed to overcome fever. The successful results noted then led him to employ it regularly after evacuation or curettage. It was found that after turpentine the pulse and temperature fell progressively during two or three days until fever was entirely gone.

The turpentine probably acts in several ways. Thus in the first place it is almost a specific antiseptic to the streptococcus, and also hinders the development of other organisms. Again, it causes a pronounced local afflux of leucocytes. Finally, it is effectually absorbed by the uterine mucosa, with its widely dilated vessels, and enters the general system, as shown by the odor of violets given off by the urine, which lasts for several days. Thus, as in the case of subcutaneous injections of turpentine solutions, the opsonic index of the blood is notably increased. The simplicity and efficacy of the turpentine treatment warrants, according to Delmas, its general adoption.

Treatment of Latent Acute Infections.—Guido Baccelli, in Paris médical for May 24, 1913, asserts that he and his coworkers have obtained excellent results in severe, obscure, acute infections by administering intravenous injections of mercury bichloride. Whatever be the true explanation of its action, he is certain that it favors destruction of bacteria and toxic substances and tends to maintain the integrity of the leucocytes. The formula he uses is as follows:

R Hydroxyrhenium chloridii corrosivi, gr. ⅓ (0.01 gramme);
Sodium chloridii, ············ gr. ⅔ (0.0075 gramme);
Aqua sterilisata, ·············· 50cc (10 grammes).
Solve.

This may be injected, in very grave cases, two or three times in the twenty-four hours. The theoretical objection that injury to the kidneys might be produced has found no justification in the author's experience. Promptly after the introduction of the mercury salt in the blood the temperature shows a fall, which may exceed one degree centigrade. At the same time the general condition is favorably influenced. Several cases are referred to in which the mercury injections unmistakably saved life.

Treatment of Pernicious Anemia.—Byrom Bramwell, in the Proceedings of the Royal Society of Medicine for May, 1913, discusses the results he has obtained with salvarsan in this disease, reporting thirteen cases. Comparing the effects with those achieved with arsenic, he is favorably impressed with salvarsan. Though he has witnessed remarkable temporary cures under arsenic, he has not seen in any series of thirteen cases such good results under arsenic as in those in which salvarsan had been given. In some cases there was no apparent benefit, but in others striking improvement. As two years is the longest time that has elapsed since treatment in any of the thirteen cases, the likelihood of recurrence cannot as yet be stated; but the author regards salvarsan as a remedy of very great use in pernicious anemia.
THERAPEUTIC NOTES.

Treatment of Diphtheria.—R. Oppenheim, in Progrès médical for February 8, 1913, advises that throughout the period of administration of antitoxine the following mixture be given daily both in order to avoid serum intoxication and as tonic:

- Calcii chloridi, ..................5iss (6 grammes);
- Syrupi aurantii, ..................5x (40 grammes);
- Spiritus frumenti, ..................3i (30 grammes);
- Tinctura cinnamomi, .............5iss (5 grammes);
- Aqua destillata, q. s. ad ...3i (100 grammes).

M. Sig.: Two tablespoonfuls a day.

The patient should be kept in a large, well ventilated room, in which a panful of water heated over an alcohol lamp, and with the addition of a tablespoonful of the following solution, should be kept constantly evaporating:

- Olei thymi, ..................6i (10 grammes);
- Olei eucalipti, ..................6i (10 grammes);
- Benzoini, ..................5i (5 grammes);
- Alcoholis, ..................Oss (250 grammes).

M. Ft. soluto.

Every three hours in the daytime, and once or twice at night, the throat should be thoroughly washed with one quart (litre) of the following solution:

- Aqua hydrogenii dioxidii, 5i (50 grammes);
- Aqua destillata, ..................Oli (1000 grammes);
- Soda boratis, ..................q. s. ut neutralisat.

Fiat soluto.

For fetid and gangrenous throats a one in 500 iodine solution, or a one in 1,000 potassium permanganate solution is preferable. To necrotic areas there should be applied, after the irrigation:

- Acidi salicylici, ..................gr. xv (1 gramme);
- Alcoholis, ..................5iss (6 grammes);
- Glycerini, ..................5vi (25 grammes).

M. Ft. soluto.

A few drops of the following should also be introduced in the nostrils:

- Eucalyptolis, ..................m.viii (0.5 gramme);
- Olei olivae, ..................3i (30 grammes).

Misce.

In severe forms of diphtheria with adynamia, a tendency to collapse, and signs of myocardial impairment or adrenal insufficiency, injections of camphorated oil, of saline solution to which epinephrine has been added, and of strychnine and stryptine may be given.

- Strychnine sulphatis, ..............gr. ½ (0.02 gramme);
- Stryptina sulphatis, ..............gr. viiiis (0.5 gramme);
- Aqua destillata sterilisata, .......5iiss (10 c. c.).

M. Sig.: Inject fifteen minims (1 c. c.) twice daily.

Powdered suprarenal substance should also be prescribed in the dose of from three to five grains (0.2 to 0.3 gramme) a day.

Treatment of Mitral Stenosis of Rheumatic Origin.—Pierret and Leroy, in Echo médical du Nord for March 25, 1913, report a case of mitral stenosis occurring on the tenth day of acute articular rheumatism in which injections of fibrolysin gave striking results. Beginning on the tenth day after the advent of the presystolic murmur, when acetylsalicylic acid had shown itself to be entirely without effect on the endocarditis, ten injections of fibrolysin, each of two cubic centimetres, were given on alternate days. By the fourth injection, the re-duplication of the second heart sound had disappeared and the presystolic murmur become almost imperceptible. The drug appeared to have acted as it does in cicatrical stricture of the esophagus or urethra. While results in a single case are not conclusive, the authors intend to repeat the procedure in subsequent cases. In the patient referred to, a return of articular swelling took place which might perhaps have been due to the action of the drug on the fibrous tissues at the joints.

Treatment of Chancroid.—Szanto, in Nouveaux Remèdes for May 24, 1913, is credited with the following ointment to be applied to chancroids after the latter have been thoroughly cleansed:

- Acidii salicylici, ..................gr. xv (1 gramme);
- Tinctura benzoini, .............5iss (2 grammes);
- Petrolati, ..................3i (30 grammes).

Misce. Ft. unguentum.

Treatment of Enteritis in Infants.—W. M. Salter, in the Southern Medical Journal for January, 1913, states that where this condition is secondary to gastric irritation, the alimentary tract should be thoroughly cleansed. Castor oil acts well if there is no vomiting; otherwise, calomel, rhubarb, and soda should be used. If vomiting is frequent and accompanied by retching, the author usually resorts to stomach washing with some alkaline solution. This is just as necessary as thorough irrigation of the lower bowels.

A twenty-four to thirty-six hour rest, only a little boiled water being allowed, is then required. In the breast fed child, it is usually safe to begin nursing on the third day, but care must be taken never to permit the child to have the full allowance of breast milk at first. The child should be given barley water or five per cent. milk sugar water before each nursing, to dilute the breast milk. This dilution should be continued throughout the excessively hot weather. In the bottle fed infant, if microscopical examination of the stools shows the proteids to be at fault, a course of barley water, whey, peptonized milk, and modified raw milk may appropriately follow the period of restriction to boiled water.

In the later stages, reduction of sugars and fats, increase of casein, and the addition of lactic acid bacteria are the measures of treatment generally suitable. The different foods used are: (1) Plain buttermilk; (2) artificial buttermilk made from the two strains of lactic acid bacilli; (3) buttermilk cooked with flour and sugar; (4) casein milk. At first the child may not like fresh buttermilk, and it may cause vomiting; but if it is persisted in, good results will appear in a few days. Buttermilk with flour and sugar is often used; one quart of buttermilk is cooked for twenty minutes, suitably diluted with barley water, and cane sugar added to make up the required calorific value. The value of this preparation seems to lie in the low percentage of fat and the presence of a different proteid, as well as of the lactic acid. Casein milk, advised by Finkelstein, is made by heating a quart of milk to 100° F., adding half an ounce of essence of pepsin, stirring well, allowing to stand at the same temperature one half hour, then filtering. The curd is forced through a fine sieve several times, and finally, one pint each of water and buttermilk added. This food has given gratifying results in all grades of intestinal disturbance. It may be given for some time, until the stools are normal and a gain in weight has begun, when return should be made to the regular milk mixture.
THE SOCIAL ASPECT OF MEDICINE.

It seems that the solution of the question of social hygiene, in the narrower sense of the word, will be accomplished by physicians rather than by social reformers. The recent epoch making developments of modern medicine, with regard to the diagnosis and treatment of syphilis and gonorrhea, have pointed to a more certain method of checking the ravages of these diseases than the former puerile and futile attempts through the control of prostitution by segregation, inspection, licensing, etc. The medical man is becoming a social benefactor, not only by the mere application of his stupendous scientific achievements, but also through his readiness and unselfish devotion to serve the cause of humanity by all means at his disposal. The efforts of the American medical profession in this respect are known to all of us. Recently, the British have taken up the matter actively. On July 22d, a letter signed by thirty-eight eminent physicians, among them Thomas Barlow, Rickman J. Godlee, William Osler, and T. Clifford Allbutt, was published in the London Morning Post. The letter points out that among the various efforts to promote health and prevent disease there is noteworthy omission, due to the criminal conspiracy of silence on the part of society as regards venereal disease. The letter calls the attention of the public to the seriousness of the problem and estimates that the new cases of the gravest form of the disease arising in the United Kingdom number a hundred and thirty thousand every year. In conclusion, an appeal is made for the appointment of a Royal Commission "to investigate the facts and to recommend what steps, prophylactic and therapeutic, should be taken to cope with these diseases." A resolution to that effect was unanimously passed by the British Medical Association and is receiving the careful consideration of the government. The International Congress of Medicine recently held in London went further in this direction by passing a resolution calling upon the governments of all the countries represented at the congress to institute a system of confidential notification of the disease to a sanitary authority, wherever such notification does not already obtain, and to make systematic provision for the diagnosis and treatment of all cases of syphilis not otherwise provided for.

The recent ruling of the Department of Health of New York city, which is in accord with the sentiment expressed in these resolutions, has not as yet the complete sympathy of the majority of the medical men of the city. It is significant, however, that when the matter of the resolution prepared by the Public Health Committee of the New York Academy of Medicine came to a vote at one of the meetings of the academy, it failed to pass by a very narrow margin only. It is to be hoped that when the advantages of notification are made more apparent, the Department of Health will have the full measure of support.

A NOVEL PROCEDURE FOR THE RELIEF OF HEADACHE.

In the Southern Medical Journal for September Dr. Max Henning, surgeon to the Memphis City Hospital, reports, with some hesitancy, a case of cure of headache of long standing following the removal of superfluous skin around the neck. The patient, it seems, was a physician, forty-eight years old, who from about the age of thirty had suffered from gastric and intestinal indigestion. After a time this became accompanied by headaches, which finally grew so severe that he was almost entirely incapacitated for his professional duties. These would occur about twice a week and last from half a day to three days, and any straining or lifting, or any sudden excitement, would at once bring one on. Hot applications to the head were the only measure that afforded even partial relief, until one occasion
Indeed, its therapeutic value in the treatment of cancer is asserting itself increasingly. The recent International Congress in London brought out a galaxy of progressive papers; few, however, received greater attention than one by Doctor Robert Abbe, of New York, on the use of radium in malignant disease. Basing his remarks on some 750 patients including 250 epitheliomas, in various regions, and 180 carcinomas of peripheral tissues, breast, tongue, throat, esophagus, etc.; fifty sarcomas of the skin, parotid, etc.; and various other types of growth, he urged that provided the gamma rays (the alpha and beta rays being removed by filtration through lead, thus producing a form of radiation analogous to x rays and of very great penetrating power) be used and correct doses be the rule, the outlook of this method of treatment was decidedly promising. There is established a retrograde degeneration of the malignant cells, which in a relatively large proportion of cases leads to a cure.

While surgical methods should continue to be given preference wherever at all possible, with radiumization of the bed of the wound to obtain degeneration of what malignant cells the exposed tissues may contain, the fact remains that radium has earned for itself the position of “next best” with fair promise to outstrip the knife. It has besides many advantages over the latter. As emphasized a few months ago by Williams and Ellsworth (Journal of the American Medical Association, May 13, 1913) the application of pure radium bromide in sufficient amount, properly used, is a painless and efficient method of treating early superficial new growths. This in itself is a distinct advantage over the knife, for a patient will almost invariably postpone surgical methods until the malignant tumor is well advanced, while practically no one would hesitate to undergo the absolutely painless exposures to radium, thus insure early treatment and increasing greatly the chances of success. Again, radium seems to be more successful when it is the first treatment employed than when it is used after operation, x rays, or other forms of treatment. In face cancers, the cosmetic results are also to be taken into account, surgical removal of a growth of the lid, lips, etc., entailing almost always a disfigurement, which radium, though equally effective, would avoid. Moreover, it does not entail the danger of burns, though destruction of tissues by radium (as Doctor Abbe has good reason to remember, through the occurrence of a trade dollar hole in his leg some ten years ago, owing to his habit of carrying radium in his trouser pockets) is not impossible through abnormally long
exposures. Such effects do not occur, however, in the course of its therapeutic use. On the whole, it is to be hoped that whether through philanthropic or other means, the use of radium will some time soon be within the reach of all.

TYPHOID EPIDEMICS.

The July number of the Journal of Infectious Diseases contains an account of a waterborne epidemic of typhoid fever occurring in a city of about 40,000 that should prove instructive. An outbreak of cases attracted the attention of the city authorities and experts were sent to ferret out the source of the disease. The investigation revealed the usual unsanitary arrangements and reckless disregard of the public health that seems so widespread here.

Apparently no attention is paid until a score or more fall ill or die. In this particular instance the examiners found conditions that would be considered dangerous by the most casual observer. An intake pipe, thirty inches in diameter, composed of wooden staves, extended fourteen hundred feet out and up the river, from whence the water supply was received. Two blocks above the pumping stations one of the largest of the main city sewers emptied into the river at a point but little below the upper end of the intake pipe. There was, therefore, the ever present possibility of a leak in the wooden pipe, and such had occurred, although it had been repaired some months before the epidemic. Moreover, changes in the water level or a diminished rapidity of the current would permit the sewage to flow directly into the intake. The consequence was that some two hundred cases of typhoid fever, with sixteen deaths, occurred. A heavy toll to pay for either ignorance or carelessness, or both! It would be well if the smaller towns and cities would examine closely into their water supply and correct faulty conditions before serious results occur therefrom.

GOAT’S MILK AND MALTA FEVER.

A bulletin has been compiled in the Bureau of Animal Industry of Washington, D. C., which is of practical interest to all who raise goats and to those people who use goat’s milk as a diet. The bulletin is based upon the now conclusively established proofs that the transmission of Malta or mountain fever to man is accomplished by the milk of infected goats. The sickness appears usually after the kidding season, during the months of April, May, and June. The general opinion is prevalent that the United States is free from Malta fever and that the disease has only occurred through importations. But it now seems evident that Malta fever has existed in Texas and New Mexico for at least twenty-five years. As is well known, the fever takes its name from the island in the Mediterranean, where the disease has been prevalent among the British soldiers and sailors. It has also been observed in other subtropical and tropical localities, among them our possessions in the Pacific Ocean. The most striking symptoms is an attack of fever with periods of normal temperature, associated with severe headache, pain in the back, and a general feeling of malaise. The mortality in man is estimated at three per cent. Pasteurization of infected milk for twenty minutes at 145° F. is sufficient to destroy the organism which transmits the disease. While the disease has no active effect on goats, its eradication must be considered important, especially as there has been lately a tendency among physicians to advise the drinking of goat’s milk for children and invalids.

WHERE DO RATS GO TO DIE?

Victor G. Heiser, the chief quarantine officer of the Philippine Islands, raises this interesting question in the Public Health Report for July 25, 1913. It is a well established fact that the rat population of any country is at least equal to that of the human. Notwithstanding the fact that the average life of the rat is only five years and that the death rate from natural causes must necessarily be great, no one has yet been able to find the carcasses of the rats in anything like the numbers which their death rate would seem to warrant. This death rate for the city of Manila should be at least 2,500 rats a month or an average daily mortality of about eighty-two rats. As a matter of fact practically no dead rats are found at all. Heiser searched all the known places where it would seem likely that the rodents would go to die without finding any of their dead bodies. As further evidence that no considerable number of rats die in out of the way places, he states that it has been the experience of the gangs of rat destroyers amounting to over 300 men, seldom to find a dead rat that has not died of poison, or from some other readily explainable cause. Live rats are frequently encountered in these operations and are promptly killed by means of dogs or clubs. Many hundreds of city blocks have been cleaned in this way, and yet it is most exceptional to find a dead rat. The contention that the dead are eaten by the living is answered by the fact that it is exceedingly rare to find skeletons of rats or any partially consumed remains. Heiser concludes that at least in Manila many hundreds of rats disappear each month by natural means, the exact nature of which is unknown, but that if it could be discovered, a useful clue might be obtained as to the best manner in which to undertake wholesale rat destruction.
THE EFFECTS OF THE DUCTLESS GLANDS UPON DEVELOPMENT.

"Despite the immense amount of work which is now being done upon the ductless glands," says Hastings Gilford, in the Lancet for September 6, 1913, "we still have to go to clinical and pathological evidence as the basis of our knowledge." Two kinds of research pursued in the study of their functions—the experimental and the pathological—tend to run along lines which are either parallel or divergent, but which can seldom be brought to a focus at any point. He contends that there is a tendency for those who approach the problem from a laboratory side to become lost in the mazes of abstract science, while those who approach from the hospital side incline to come prematurely to conclusions which are unscientific. In order to be practical and to get at the truth, Gilford thinks that we must turn to pathology for most of our information. "The normal action of these glands is so delicate, so complex, and so abstruse that we can best judge of what happens in health by drawing inferences from that which takes place when their action is magnified or diminished by disease." Acting upon this basis, Gilford discusses the relation of these glands to development, remarking that the problem is that of studying the inhibition or the reinforcement of those bodily correlations which are carried on through the medium of chemical secretions or hormones.

In the matter of development the initial correlations are possibly set going by the mechanical penetration of the spermatozoan into the ovum, and they probably continue for a considerable time, before the ductless glands are developed, without the influences of these glands, and it is highly probable that some faculty of adjustment and correlation persists throughout life which is quite apart from the action of the nervous system or the ductless glands. Thus it is hard to understand the adjustments which occur in achondroplasia, in rickets, and microcephaly unless we adopt some explanation which leaves out the ductless glands. Though the ductless glands are of great importance, we are led to suppose, therefore, that they are only a part of the machinery of adjustment.

AN APPENDIX OF UNUSUAL SIZE.

At a recent meeting of the Medical Society of Montpellier, France (Revue de Chirurgie, August, 1913), A. and M. Romieu exhibited the appendix of a young man who had succumbed to septicaemia, measuring no less than twenty-four centimetres (ten inches) in length. The organ was found extending into the pelvis, and was compressed near its inferior extremity by an adhesion which held it against the pelvic wall near the rectum and had produced a terminal cystic dilatation. The lumen was otherwise almost entirely free, and contained near the lower end of the organ, above and below the constricted section, a small quantity of fecal matter, not in the form of concretions, and about twenty fig seeds with their pericarps or akenes.

The Wesley M. Carpenter Lecture.—This lecture was given on Thursday evening, October 16th, at a stated meeting of the New York Academy of Medicine, by Dr. William H. Park, of the Department of Health of the City of New York, his subject being Antitoxin Dosages, Anaphylaxis, and Active Immunization Against Diphtheria.

Appointments at the University of Pittsburgh.—Among the new appointments made at the University of Pittsburgh for the coming year are the following in the school of medicine: Dr. J. H. Heard has been appointed professor of medicine, Dr. X. O. Werder, professor of pathology, Dr. J. M. H. Elliott, assistant professor of clinical pathology; Dr. C. Gardner, assistant demonstrator in anatomy.

Clinical Lectures on Diseases of the Skin.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley will give the fifteen series of clinical lectures on diseases of the skin in the outpatient hall of the hospital, on Wednesday afternoons, at 4:15 o'clock, beginning on November 5th. These lectures will be free to the medical profession on the presentation of professional cards.

Medical Society of the County of Dutchess, N. Y.—A bi-annual meeting of this society, held on the afternoon of Wednesday, October 8th, the following officers were elected: Dr. L. C. Wood, of Poughkeepsie, president; Dr. R. H. Breed, of Wappingers Falls, vice-president; treasurer, Dr. Lewis H. Marks, of Poughkeepsie; secretary, Dr. F. J. Knowles, of Riverdale, and Dr. Howard Carpenter, of the Hudson River State Hospital, Dr. J. H. Cotter, of Poughkeepsie, and Dr. D. H. MacKenzie of Millbrook.

Professor Schmidt to Lecture in New York.—Dr. Adolph Schmidt, professor of medicine in the University of Halle, Germany, will deliver the tenth annual Schmidt lecture on Saturday evening, October 18th, at 8:30 o'clock, at the New York Academy of Medicine, his subject being Severe Anemia in Gastrointestinal Diseases. He will also deliver a lecture on Clinical Gastrointestinal Diseases, at the Postgraduate Medical School and Hospital on Tuesday, October 21st, at 4 p. m. All members of the medical profession are invited.

Norwegian Hospital Alumni Association.—This association, which was organized fifteen years ago, met in the hospital building on Wednesday, October 8th, Dr. G. H. V. Hunter read a paper on Sex Determination, Dr. C. E. Lack spoke on percentage infant feeding, and Dr. R. E. Coughlin paid a personal tribute to the late Dr. Cushman Turner, formerly dean of the medical staff. The officers of the association present were Dr. George Moore, president; Dr. Louis Stork, vice-president; Dr. Henry Spelman, secretary and treasurer.

Meetings of Medical Societies to Be Held in Philadelphia During the Coming Week.—Monday, October 20th, Philadelphia Clinical Association, Medical Society of the Woman's Hospital, and the Northwestern General Hospital Medical Society; Tuesday, October 21st, West Branch of the Philadelphia County Medical Society, and the Philadelphia Laryngological Society; Wednesday, October 22nd, Philadelphia County Medical Society; Thursday, October 23rd, Pathological Society and the Germantown Branch of the Philadelphia County Medical Society; Friday, October 24th, Neurological Society, Northern Medical Association South Branch of the Philadelphia County Medical Society, and the directors of the Medical Club.

The Medical Association of the Greater City of New York.—A stated meeting of this association, the first of the season of 1913-1914, will be held in Du Bois Hall, New York Academy of Medicine, on Monday evening, October 20th, at 8:30 o'clock. The programme will include the following papers: Tuberculosis Patients Treated by a New Method and By C. A. Enders; Theory and Treatment of Diabetes, by Dr. William Edward Fitch; Diabetes Azoturique of the French, by Dr. Anthony Bassler; Diabetes in Children, by Dr. Louis Fischer. Among those present will take part Drs. R. E. Cornwell, Dr. Robert L. Watkins, Dr. J. Wallace Beveridge, Dr. Charles Herrman, and Dr. Eli Long.
Dengue in Savannah, Ga.—Surgeon C. H. Lavinder, of the United States Public Health Service, reported by telegraph on October 8, 1913, that dengue was prevalent in Savannah, Ga.; the number of cases of the disease was not known.

Cholera in Rumania.—During the week ending September 11, 1913, there were reported in Rumania 401 new cases of cholera, with 165 deaths, making a total from the outbreak of the disease of 1,452 cases, with 623 deaths. In the last week of this period 25 new cases of cholera were reported on September 11th at Silistria among Greek and Turkish refugees.

Honorary Degrees Conferred by the University of Birmingham.—At the annual meeting of the British Association held recently in Birmingham, England, the honorary degree of doctor of laws was conferred upon several foreign guests, among them being Doctor Arthenius, director of the Nobel Institute for Physics and Chemistry, at Stockholm; Madame Curie, director of the Physiological Laboratory at the Sorbonne, Paris; Doctor Kelbel, professor of anatomy in the University of Freiburg, Germany; Dr. H. A. Lorentz, professor of physics in the University of Leyden, and Dr. R. W. Wood, professor of experimental physics in the University of Michigan.

The Eastern Medical Society.—A symposium on the education of the public in regard to cancer was presented at a meeting of the Eastern Medical Society, held on Friday, September 10th, in Philadelphia. The Symposium of Malignancy, by Dr. Howard Lillienthal; Cancer in Women, and the American Society for the Control of Cancer, by Dr. Le Roy Broun; Some Cancer Problems in Greater New York, by Frederick L. Hoffman, F.C.S.; and Cancer, by Dr. John A. Bodine, Dr. Louis J. Ladinsky, and others. The meeting was open to the public and there was a good attendance.

American Radium and Ray Society.—The fourteenth annual meeting of this society was held in Boston on October 1st, 2d, 3d, and 4th, under the presidency of Dr. H. K. Pancost, of Philadelphia. About one hundred physicians from the United States and Canada were present. An excellent programme was presented, and an interesting feature was a symposium on the value of the x ray in the diagnosis of diseases of the stomach and duodenum. Among those who contributed to the symposium were Dr. Lewis Gregory Cole, of New York, Dr. A. W. George, of Boston, Dr. S. F. Pfahler, of Baltimore; Dr. J. J. Case, of Battle Creek, Mich., and Dr. F. H. Baetjer, of Baltimore. Many of the papers were illustrated by lantern slides.

Personal.—Dr. John R. Shatterly, of Boston, has been elected King of the Royal Society of Physicians of the New York X.

A New Hospital Building for Temple University.—Plans have been arranged whereby Temple University, Philadelphia, will have the largest hospital, not a government or municipal institution, in the United States. The Philadelphia College at Eastwick and Bottonwood Streets will be moved to one of the other Templebuildings and the building now occupied by the dental, pharmaceutical, and medical departments added to Garretson Hospital, with one hundred and fifty-two private rooms. The surgeons will meet in the auditorium, and a new ward will be built an entire new hospital, with one hundred and twenty-five private rooms, which, in addition to Samaritan Hospital and the Garretson Hospital, will give the medical students of Temple University unrivaled facilities. At present, Temple has about 1,111 members; the State of Pennsylvania is now constructing a laboratory building, a memorial to the late Dr. Elmer E. Brown, for many years vice-president of the university.

New York and New England Association of Railway Surgeons.—The twenty-third annual meeting of this association will be held at the Hotel Astor, New York, on Wednesday, October 22d, under the presidency of Dr. John W. Le Seur, of Batavia, N. Y. There will be two sessions. At the morning session the annual address of the president will be delivered by Dr. Ralph E. Trust, of Buffalo. Mr. Ralph Peters, president of the Long Island Railroad, will deliver an address. In the afternoon Dr. Hugh E. Young, of Baltimore, will deliver the address in surgery. At the evening session the address of the vice-president, Dr. C. A. Pease, of Burlington, Vt.; second vice-president, Dr. W. H. Marcy, of Buffalo; corresponding secretary, Dr. George Chaffee, of Brooklyn; recording secretary, Dr. J. H. Reid, of Troy, N. Y.; treasurer, Dr. J. N. Sloss, will be delivered.

Section in Obstetrics and Gynecology of the New York Academy of Medicine.—The meetings of this section will be held in future on the fourth Tuesday of the month, instead of on the fourth Thursday as heretofore.

At the next meeting, which will be held on the evening of October 28th, the programme will be furnished by the staff of the Lying-in Hospital. Dr. E. S. Gushée will present a review of the obstetric problems that have been brought under the care of the Arnold Founders Hospital during the past five years will be presented by Dr. Ross McPherson. Papers will be read as follows: Additional Experiences with the DilaYSation Method for the Sterilization of Pregnancy, by Dr. C. F. Jellinghaus and Dr. H. H. Losee; Magnesium Sulphate Treatment of Puerperal Streptococcemia, by Dr. J. A. Harrar. A general discussion will follow. Dr. George Gray Ward, Jr., is chairman of the section and Dr. George W. Kosmak is secretary.

State Medical Society of Wisconsin.—Dr. Charles Sheldon, of Madison, was elected president of this association, at the annual meeting held recently in Milwaukee. Other officers were elected as follows: Dr. C. A. Evans of Milwaukee, first vice-president; Dr. E. J. Combs, of Madison, second vice-president; Dr. J. M. Elkhorn, third vice-president; Dr. J. P. McMahon and Dr. A. W. Gray, of Milwaukee, and Dr. F. F. Bowman, of Madison, committee on public policy and legislation; Dr. M. P. Ravenel and Dr. C. Harper, of Madison, Dr. Gilbert M. Stordahl, of Lodi, Dane County, Dr. O. B. Finney, Dr. Thomas 1lay, of Stevens Point, committee on prevention of tuberculosis; Dr. Edward Evans, of La Crosse, Dr. E. S. Hayes, of Eau Claire, and Dr. W. H. Washburn, of Milwaukee, committee on medical education; Dr. A. W. Michelson, of Milwaukee, Dr. C. Reynolds, of Lake Geneva, and Dr. E. L. Boothby, of Hammond, committee on neurology; Dr. C. A. Bardeen, of Madison, delegate to act with the board of public instruction; Dr. C. A. Patock, of Milwaukee, delegate to the national legal council; Dr. H. H. Hitz, delegate to the council of medical education; Dr. J. M. Dodd, of Ashland, delegate to the American Medical Association.
Pith of Progressive Literature.

MUNCHENER MEDIZINISCHE WOCHENSCHRIFT.

Prophylactic Ferments as Specifics. The Blood Serum of Pregnant Animals; Its Relation to Different Organs.—E. Abderhalden and E. Schiff state their result of tests with the blood of over five hundred pregnancies of women and animals. Another organ was always used as a control along with the placenta. They proved that the prophylactic ferments have a specific action. In about one hundred and five examined patients there was a disintegration of the hepatic tissue. In about thirty other patients there was a disintegration of the thyroid gland. The more accurately the experiments were conducted, all errors being eliminated, the more convincingly were the prophylactic ferments proved to be specifics. In organs free from blood the reaction was negative. The serum of a patient with severe contusion of muscular tissue and a large hematoma showed disintegration of neither the liver nor the placental tissue by the action of the prophylactic ferments; but a very marked solvent action on the muscle tissue was observed. When the technic was carefully observed decomposition of no organ takes place except the placenta and other organs containing blood. In this connection it may be added that, at the Physiological Institute, all the organs of one hundred healthy horses, cows, and pigs were tested with the prophylactic ferments. In three per cent. of all cases the organs were disintegrated. Generally it was the liver which gave a positive reaction, although possibly some parts of it contained blood, it being difficult to keep the liver free of blood.

Pause in Audible Breathing.—R. Geigel, in his analysis of respiration, finds that in healthy people there is no respiratory pause between the act of inspiration and expiration; real pauses occur only in pathological conditions. The seeming pause in audible respiration of the healthy is not in reality a pause, because respiration continues even though it cannot be heard. In patients with fever respirations are more rapid. The pause ceases and returns when breathing becomes slower. It grows clearer, longer, and deeper with a decline in the temperature. When one can observe the existence of pauses, whether marked or absent, it is possible to estimate any increase in number without counting. This is of value at times when, on account of crying, coughing, or talking, one cannot count the respirations at all. In listening to five sick infants under fourteen months old, the author detected pauses between each respiration which numbered twenty-six to the minute; shorter pauses in thirty to the minute; none at forty-two nor at fifty, and after about one hundred such observations are made it is easy to distinguish whether the respiratory count is dependent upon age or disease solely by the presence or absence of the pause.

A New Leucemia, Splenocytic Leucemia, and Its Significance in the Independent Life of Its Cells.—H. Reschad and V. Schilling contribute the following modern classification of systemic leucemias: myocytic and lymphatic, either acute or chronic. The present form, according to the authors’ observation, are acute leucemias with large mononuclear and transition cells or splenocytes of independent growth. This is therefore designated as independent splenocytic leucemia. This places a new systemic leucemia along with the myelogenous and lymphatic varieties.

Serology in Psychiatry.—A. Fauser states as a result of his experiments that aside from the disturbed function of the thyroid and other ductless glands, the cells of the cortex are found to be imperfectly functioning. The disturbed function of each organ is shown in various ways. This is well known of the thyroid gland, as in one instance a Basedow psychosis is seen and in another a different psychosis develops. The same may be said of the placenta and other glands with internal secretion. Each organ and cell is one of internal secretion. It may be assumed that the differential diagnostic significance of serological findings may have to be narrowed down to the process of dialysis for the present. It is to be hoped, and Abderhalden’s investigations with respect to normal and pathological pregnancies make it probable, that this method will give us knowledge of the different forms of disturbed function. Then also, for instance, the key to diagnosis, which may be drawn from the different forms of gland cells, will become more simple. We are as yet at the beginning of a new and important investigation. It will require much work to solve this great problem. Our large insane asylums which have housed the sick each have a staff who for many years have observed the different stages of development of the inmates’ diseases. These are specially called to aid in their branch of the work.

Metabolism in Mental Diseases.—A. Bornstein, from the results of his experiments during the past ten years, concludes that there exists a disturbed function of the sexual glands in dementia praecox and that the decreased function brings about a pathological mental exaggeration at puberty, and accordingly we have a disturbed metabolism which expresses itself in a psychic derangement. The author’s former conclusions coincide with the results of Abderhalden and Fauser, who found that the serum, in dementia praecox, decomposes sexual gland substance, and at the same time there is a disturbed function of the internal secretion of the ovaries and testicles.

Contribution to Infantile Paralysis.—J. Brunt reports the history of some patients living in isolated districts, where some animal belonging to the family, as a dog, goat, chicken, or cow, died of paralysis. As these sporadic cases had come in contact with no other children, it is assumed that in each case the patient’s infection could be traced only to the animals of the respective households that had died of paralysis shortly before.

Radiological Studies on the Function of the Stomach.—F. Eisler and R. Lenk conclude the results of their experiments with lecithin as follows: Neither the chemical production of the gastric juice nor anomalies in the vegetative nervous system, either alone or combined, effect
any constitutional disturbance in the motor function of the stomach.

September 23, 1913.

Experimental Arteriosclerosis and Cholest erinemia.—L. Wacke and W. Hueck contribute the following: By increasing the cholesterin content of the blood in rabbits for a month it was possible to bring about a diseased condition of the aorta which resembled sclerosis of the aorta in man. This would suggest hypercholesterinemia as a pathogenetic in human arteriosclerosis. They have also found through animal experimentat that excessive nourishment and muscular exercise, dyspnea, certain poisons, epinephrin, and extirpation of the suprarenal capsule, all produce a powerful influence on the increase of the cholesterin content of the blood.

Thorium X in Internal Diseases.—O. Meseth demonstrates from his experiments that in anemias (except the pernicious form) in sciatica, as well as in secondary chronic joint affections, the treatment with thorium x is thoroughly effective. The author therefore wishes to strongly recommend its use in these diseases, especially since its effects appear to be superior to the therapeutic measures used heretofore. The use of thorium x may be carried out in general practice. It is only necessary to have it freshly prepared on the day of its use. A continuous leucocyte count is not only desirable but, in the author's opinion, indispensable.

ZENTRALBLATT FÜR CHIRURGIE.

September 6, 1913.

Treatment of Syndactyla.—Guido Lerda reports a case which he treated successfully by the division of the web and the interposition of Thiersch flaps over the entire raw surface.

FOLIA UROLOGICA.

Kidney Stones.—Illyes has observed eighty-one and operated on sixty-three patients with kidney or ureter stones. In some of the cases the so called "crossed colic" has been observed, the stone being on one side and the colic being referred to the other. Occasionally the ureter of the affected side showed abnormality, swelling, bulbous edema, etc. Functional methods, especially cyroscopy, showed a decreased function of the affected kidney. If the kidney is infected and the condition has persisted for a long time the opposite kidney may show a toxic nephritis; such a condition does not prevent the removal of the stone kidney. Occasionally the radiograph is negative but the stones are found at operation. The operations of choice are either pyelotomy, or, if the kidney is much destroyed, nephrectomy. Nephrotyotomy is performed only when pyelotomy is impossible. In one of the author's cases of anuria which had persisted for four days he introduced a urethral catheter nine centimetres up the ureter of the affected side and met an obstruction. He injected ten centimetres of sterile oil through the catheter, and in four hours the patient voided 550 c.c. of oily urine; the stone which passed into the bladder was removed later. In another case he did a unilateral nephrectomy. The anuria had persisted eight days. The patient voided plenty of urine through the wound made by the nephrotomy; but three days later anuria again set in and the patient died.

Two Cases of Nearly Complete Removal of the Bladder for Tumor.—Nicolich removed nearly all of a carcinomatous bladder, leaving the trigone, in a patient seventy-two years old. The entire bladder space was plugged and the peritoneum was sewed to the upper margin of the abdominal incision. Fifty-two days after the operation the patient was able to urinate every three or four hours and able to completely empty his new formed bladder. He was well up to ten months after the operation. In a second patient, forty-four years old, who had been operated upon twice before for multiple papilloma the same operation was performed. The patient recovered and twenty-two days later the wound was closed and the patient urinated normally every four or five hours.

Tuberculosis of the Prostate.—A. Gotzbelieves that the prostate is almost always secondarly infected by tuberculosis. This secondary infection takes place by the blood, the lymph, or by contact. If by means of the blood stream the prostate is alone attacked, or simultaneously with the kidney, seminal vesicles, or epididymis. Infection through the lymphatics always follows the direction of the lymph stream. Infection by contact is always secondary to infection of the kidney, seminal vesicles, or epididymis. Most cases develop during the period of sexual activity. Any persistent urethral discharge not due to the gonococcus excites his suspicion of tuberculosis of the prostate. He has found that general treatment, for tuberculosis, local and tuberculin treatment, are alike effective in coping with this disease. He believes in prostatectomy, although he says in some cases that dissecting out the fistula and curing the prostate give good results.

Bladder Cysts.—R. Hottinger describes a rare case of a cyst of the anterior bladder wall of the size of a cherry. The patient was forty-six years old; had pain on urination and a residuum of from 100 to 200 c.c. There was no stricture present and the prostate was normal. The cystoscope revealed the cyst; which was removed by cystotomy. The cyst was probably an enlarged bladder gland.

Bladder, Prostate, and Urethral Stone.—P. Steiner has performed lithotomy in twenty-eight patients thirty times; two patients requiring a second operation for return of the bladder stone. One of these returned one year after the first operation and the other four years, and the cases were complicated by prostatic hypertrophy (not operated on). Two patients died: One a sixty year old man with diabetes and prostatic hypertrophy not operated on). Two patients died: One a sixty year old man with diabetes and prostatic hypertrophy; and the other a seventy-six year old man with prostatic hypertrophy. Fourteen cases occurred between the ninth and thirteenth year. He did a cystotomy on forty-two patients forty-six times; four patients requiring a second operation. In nine patients prostatectomy and removal of the stone were performed through the suprapubic incision; two of these nine died because of the prostatectomy. Twenty-five cases in which cystotomy was done occurred between
the ages of one and one half years and fifteen years. His mortality, without counting the prostatectomies, was 3.8 per cent. (seventy-six operations); counting the nine prostatectomies, the mortality was 5.7 per cent. In addition to this the author has operated three times for stone in the prostate and seven times for stone in the urethra, with two deaths from uremia.

Simple Bladder Ulcer.—L. Buergers reports two cases of simple callous ulcer of the bladder. The clinical symptoms are dysuria, urgency, frequency, hematuria, and pyuria. The course which they ran was chronic. The author believes that chronic cystitis and contracted bladder are often caused by solitary ulcerations. They are most frequently found in the trigone. Cauterization or fulguration are of no use in the treatment of this type of ulceration which should be excised by means of the "author's operating cystoscope and punch forceps." (Is it possible that another operating cystoscope might do as well? Editor.) Histological examination showed a characteristic pathology, there being a superficial deposit of urinary salts, a layer of necrosis and ulceration, and a stratum of newly formed connective tissue, with active evidence of inflammation. The margin of the ulcer showed intense vesicular and inflamed mucosa and submucosa.

Stricture of the Urethra and the Genital Function.—G. F. Demo says that inflammatory strictures of the urethra are apt to alter or abolish the sexual function. If the urethra does not remain elastic and contractual erection is hindered, there may be delayed ejaculation, sterility, impotence or atrophy of the testicles.

The Relation between Abnormality of the Kidney Vessels and Hydronephrosis.—J. Borelius believes that abnormality of the kidney vessels of the lower part of the kidney hilus can influence the development of the hydronephrosis if entering the posterior part of the hilus before the ureter, or the anterior part of the hilus behind the ureter. He also believes that there is another factor in every case which is probably that of the mobility of the kidney. These two together cause the pelvic dilatation.

Carcinoma of the Prostate, Bladder Stone, Congenital Stenosis of the Ureter, Etc.—F. Putzi had a patient forty years old who since his tenth year had painful urination. On entering the hospital the patient was marasmic; had intense pain in the hypogastrum and perineum; had pyuria, hematuria, and dysuria; a large mass could be felt in the bladder and a swelling and tumor of the right hypochondrium. The patient was operated upon and a 214 gramme stone removed suprapubically. He died forty hours later. Autopsy showed carcinoma of the prostate with metastasis of the bladder and lymphatics, stricture of the urethra, congenital ureteral stricture, and pyonephrosis of the right kidney.

Endovesical and Endourethral Treatment with the High Frequency Current.—R. Bachrach has, after the method of Beer, used the high frequency current in twenty patients who had papillomatous growths after cystotomy for removal of these. The patients have remained free from recurrence for more than a year. He says that the method is not practical for large and extensive papilloma or carcinoma.

ZEITSCHRIFT FÜR UROLOGIE.

Supernumerary Ureters.—Hartmann reports a female patient of thirty-three years who had been treated for incontinence of urine since early childhood. No physician had discovered the very small ureteral opening just below the orifice of the urethra. Colored fluid injected into the minute fistula did not color the urine in the bladder and a vaginal incision showed the ureter running to the right kidney. The lower dilated segment was cut and the ureter implanted in the bladder wall. The recovery was uneventful.

Staphylococcus Infection of the Urinary Passages.—Goldberg says that, as a rule, staphylococcus infection is of brief duration and easily cured. Chronic infection is rare and is generally secondary to marked phosphoruria, or occurs after gonorrhea; albuminuria accompanies it. If the kidneys are attacked the resulting sepsis is dangerous; Oten had 80 per cent. mortality in twenty-two cases, and Bettemann 70 per cent. mortality. The symptoms which Goldberg's first four cases gave were tenesmus and pain on urination, urinary frequency, scanty and turbid urine filled with epithelial cells and cocci.

Cystic Dilatation of the Vesical Part of the Ureters.—Rumpel reports a case of a young woman of twenty-five who had polyuria and dysuria. A cystoscopic examination showed both ureteral orifices much enlarged and cystic in appearance when urine was excreted, and collapsing between times. He operated suprapubically, put catheters into the orifices of the cysts, cut away the bladder mucous membrane and sewed the mucous membrane of the ureters to that of the bladder.

LYON MÉDICAL.

Traumatic Acute Anterior Poliomyelitis.—A. Gomnet and R. Rendu report the case of a boy seventeen years of age, probably but not certainly, with a congenital syphilitic taint, in whom, after he had been struck violently at the junction of the cervical and dorsal portions of the spine by a cart, there developed signs of pure, uncomplicated degeneration of the anterior horn cells, viz., muscular atrophy in all four limbs, reaction of degeneration, and fibrillary contractions, without evidences of pyramidal or sensory involvement. They believe it likely that congenital syphilis acted as a predisposing cause in the development of the acute diffuse poliomyelitis which followed the traumatism.

PARIS MÉDICAL.

Treatment of Chancroidal Bubo.—H. Costantini recommends the following procedure in the treatment of chancroidal buboes that are about to
or have already “pointed” : After painting the skin with tincture of iodine make a stab incision from four to five millimetres long at the point of most distinct fluctuation. Evacuate the pus cavity by gentle pressure, and inject into with a syringe a one per cent. solution of silver nitrate. The syringe should not be withdrawn for three or four minutes, in order that the solution shall be held in for this period of time. The solution is then allowed to run out, no direct pressure, however, being exerted. A piece of silkworm gut, doubled upon itself, is then introduced into the cavity as deeply as possible, and a tight dry dressing applied. The same procedure is gone through on the second day, and if it be thought desirable, on the succeeding days until the seventh, when, after injecting the silver nitrate solution, silkworm gut need not be reinserted. Recovery is practically complete by the tenth day, though a drop of serous fluid may exude upon pressure a few days longer, and a protective dressing, to be changed every two or three days, should therefore still be used for a time. In case drainage proves imperfect in using this form of treatment, a grooved director should be introduced through the incision and obstructing tissues broken up. The advantages of the treatment are that it is simple, requiring no special instrumentation or surgical skill, and that healing takes place very promptly, with practically no residual scar.

**August 30, 1912.**

**Vibropalpatory Method of Estimating the Blood Pressure.**—Finck points out that when the arm circulation is gradually occluded, the lower brachial pulse being simultaneously palpated, a series of pulsations of increasing amplitude are felt, followed suddenly by a single very distinctly vibrating, whiplike pulsation, and then by a series of pulsations of less and less vibratory character, until the pulse weakens and finally stops completely. In taking the blood pressure the observer holds the brachial artery below the cuff against the humerus, pumps air into the cuff until the first vibrating pulsation is felt, reads off the pressure on the mercury or dial manometer, continues pumping until the pulsations cease, then lets air out gradually, noting the pressure at which the pulse loses its vibratory character. This pressure averages five mm. lower than the first. The mean of these two pressures is taken, and indicates, within two or three mm., the diastolic blood pressure in the subject under examination. Five minutes later, in order to ascertain the systolic pressure, air is pumped in until the pulse ceases, the pressure at which this occurs noted, the pressure raised one cm. more, decompression then begun, and the pressure at which the first returning pulsation appears observed. The mean of the two figures is the systolic pressure. In this method, when a dial manometer is used, the first vibrating pulsation is found to coincide with the first large oscillation of the needle. In practical work, however, it is often easier to feel the first vibrating pulsation than to detect the first large oscillation—an advantage of the author’s procedure over the frequently used oscillatory method of estimating the diastolic blood pressure.

**Device to Prevent Air Embolism in Giving Intravenous Injections.**—P. Barthélémy and G. Bossy describe a small attachment for the “606” apparatus consisting of an ovoid glass bulb into one extremity of which enters a small glass tube, which dips down to the lowest part of the bulb. The outer end of this small tube fits into the platinoiridium needle which is introduced into the vein, while the other extremity of the bulb carries a glass cock and is connected with the tube leading from the receptacle for the fluid to be injected. Before starting the injection the bulb is turned upside down and the cock opened. Some of the solution runs into the bulb, and any air in it, collecting at the top, escapes through the small tube. The cock is then closed, the bulb returned to its normal position, the needle introduced into the vein and connected with the bulb, and the cock reopened, allowing the solution to flow into the vein. Any small air bubbles that have remained in the rubber tube until this time are now automatically caught in the upper portion of the bulb, and cannot possibly enter the circulation because of the fact that the small outlet tube dips down to the bottom of the bulb.

**Coma of Cerebellar Origin.**—G. Milian and E. Schulmann report a case of cerebellar softening with autopsy, and formulate, from their observation of it as well as a study of a few related cases found in literature, the cardinal signs of coma of cerebellar origin as follows: (1) Conjugate deviation of the head and eyes, the former downward upon the chest and the latter under the lower lids; (2) nystagmus, with very slow and vertical oscillations; (3) marked depth of the coma, out of proportion, it would seem, with the extent of the cerebellar lesion; (4) intense general contracture, suggesting meningeal hemorrhage; (5) bilateral corneal anesthesia, with bilateral loss of abdominal and cremasteric skin reflexes; (6) bilateral extension of the toes in Babinski’s test; (7) Cheyne-Stokes breathing, more or less typical; (8) progressive rise of temperature up to a very high level, even over 42° C.; (9) lumbar puncture showing a slight rise in pressure, but no lymphocytosis or blood in the event that softening is the cause of the condition. In the case reported the lesion was limited to the superoanterior and superomesial cortex of the left cerebellar lobe, all other portions of the central nervous system being normal.

**Support for the Upper Extremity in Traumatic Cases.**—Dupuy de Frenelle takes two strips of cloth, each twenty centimetres wide, sews the end of one to the centre of the side of the other, forming a T. encircles the forearm, hand, and chest horizontally with the strip representing the upper limb of the T, passes the other under the forearm and up in front of the chest, and splits it longitudinally into two portions, which are passed over the shoulders and fastened to the horizontal strip behind.

**Laxity of the Fingers as an Index of the Mobility of the Coccyx.**—L. Planter asserts that in women with loosely jointed fingers backward rotation of the coccyx to admit passage of the fetus during labor always takes place easily, while in parturients with closely knit and rigid digital joints
the coccyx regularly offers considerable resistance to the presenting part, thus greatly delaying the terminal stage of labor and causing alternate marked advances and recessions of the child before the head finally passes the perineum. Examination of the fingers of the patient has often enabled the author to reassure old primiparae who dreaded a slow second stage, and on the other hand to realize the advisability, even in certain young women, of resorting early to instrumental intervention and thus avoiding prolonged, fruitless efforts on their part.

**PRESSE MÉDICALE.**

**September 6, 1913.**

**Cultural Studies on the Virus of Rabies.**—H. Noguchi describes the corpuscular bodies observed by him in cultures from the brains and cords of animals inoculated with rabies. Photomicrographs are reproduced showing nucleated corpuscles, of protozoan appearance, dividing actively, the products of fission or budding remaining for a time in a common sheath, then being replaced by numerous small granular bodies and still smaller free corpuscles. Inoculation of dogs, rabbits, and guineapigs with these bodies reproduced the disease.

**September 10, 1913.**

**Effect of Artificial Pneumothorax on the Lung of the Opposite Side.**—R. Burmard asserts that artificial pneumothorax, as employed in the treatment of pulmonary tuberculosis, has but little influence on the opposite lung. If the latter is healthy or embodies only mild or latent foci of disease, pneumothorax seems to improve its function and exert a favorable effect on the tuberculous lesions. If the opposite lung is seriously involved, with rapidly progressing foci, the procedure is contraindicated. Where it is the seat of extensive but sluggish disease, pneumothorax does not appear to affect it markedly either for better or worse. In a very few instances, artificial pneumothorax causes serious progression of the disease areas in the opposite lung; but this appears to be due almost always to a too rapid or copious introduction of gas. Much more frequently the opposite side shows signs of a mild congestive condition, very often in the regions of the basal pleura or the interlobar fissions. This complication must probably be attributed, in the majority of instances, to a pleuritic process developing on the operated side, or, again, to excessively sudden and dyspnea producing insufflations.

**SEMAINE MÉDICALE.**

**September 10, 1913.**

**Calcium Estimation and Its Diagnostic Significance.**—G. Rodillon describes a simple, “bedside” technic for the estimation of the calcium excreted in the urine. Excessive calcium elimination, being an early manifestation of tuberculosis, may be a diagnostic sign, where the physician does not suspect or is in doubt as to the presence of this disease. The material necessary for the “calcireaction” consists of: 1. A flat bottomed glass cylinder, fifteen millimetres in diameter, graduated in cubic centimetres; 2. a dropper yielding twenty drops to the cubic centimetre of water; 3. a white plaque or card upon which has been traced with black ink a straight line two or three millimetres in cross section; 4. a reagent consisting of pure neutral ammonium oxalate, three grammes; glacial acetic acid, five grammes; and distilled water, forty grammes. To calibrate the cylinder, it is filled to the five c. c. mark with the oxalate solution, then to the ten c. c. mark with a solution consisting of 0.357 grammes of C. P. calcium carbonate, one gramme of acetic acid, and distilled water, enough to make one litre. After mixing and allowing to stand five minutes, the tube is placed vertically over the black line on the card, and some of the mixture removed with the medicine dropper until the line just becomes visible through the precipitate of calcium oxalate. The figure then read off on the tube—approximately 2.4 c. c.—when divided by 5, remains a constant for subsequent urine examinations. In testing urine, the same procedure is gone through, urine being, of course, introduced instead of the calcium carbonate solution. The figure read off, say 3.2 c. c., is divided into the constant, 0.48(=2.4÷5) and the result, say 0.15, constitutes the amount of calcium oxide in one litre of the urine tested. On a mixed diet the normal adult eliminates from 0.35 to 0.5 gramme of lime daily in the urine. Where the test shows an excretion of 0.7 gramme on a mixed diet, 0.5 gramme on a vegetarian diet, or 0.9 gramme on a meat diet, calcium demineralization, suggestive of tuberculosis, is indicated. Results below these figures but above 0.5, 0.3, and 0.7 gramme, respectively, are suspicious.

**September 17, 1913.**

**Diagnosis of Tuberculous Salpingitis.**—R. de Bovis, after enumerating the various recognized diagnostic features of tuberculous salpingitis and showing that none of them is very reliable in actual practice, discusses a sign of this affection first described by Bazterrica, viz., periodically increased and then decreased size of the tuberculous annexal tumors, due to temporary obliteration of the tubal lumen or evanescent congestion. The last named condition may be brought on by digestive disturbances, venereal excesses, or other similar causes. The sign is doubtless not strictly pathognomonic of tuberculous disease, but its value has been confirmed by several observers, and in view of the lack of other good diagnostic indications is worthy of some degree of attention.

**REVUE DE CHIRURGIE.**

**August, 1913.**

**Treatment of Old Fractures of the Patella.**—E. Quenu and J. Gatellier term “old” fractures of the patella those in which six weeks to two months or more have elapsed since the accident. At this period, if any separation of the fragments exists, absence of bony callus is the rule. The two fragments are covered with fibrous tissue and have become smoother and shorter by reason of partial absorption. Retraction of the fibrous tissue may have occurred, hindering flexion of the knee and becoming associated with arthritis, which soon leads to atrophy of the quadriceps muscles. In the treatment the chief desideratum is to obtain coaptation of the fragments. In simple cases this may be accomplished by the same operations as are performed in
recent fracture, care being taken, in addition, to free from fibrous tissue and freshen the bony surfaces to be apposed. Where traction does not suffice to bring the fragments together, V shaped incisions should be made in the quadriceps, or the muscle even severed more or less deeply. If these manoeuvres fail, provided the separation does not exceed one centimetre and the patellar tendon is intact, coaptation may be secured by detaching the tibial tubercle and implanting it above its normal situation. If the separation exceeds one centimetre fibrous and muscular autoplasty should be resorted to. The best technic is that of Ferraresi, which is simple and yields perfect and prompt results. It consists in dissecting from the quadriceps, just above the patella, a flap of tendon two millimetres thick and of the length of the patella, turning the flap downward in front of the bone, and suturing its margins to the patellar ligament and the firm fibrous tissue covering the bone. Among seventy-four cases of old patellar fracture collected by the authors from the literature—all operated since 1893—excellent results were noted in eighty per cent., almost perfect results in seventeen per cent., and failure or death in three per cent.

**Pulmonary Tuberculosis and Surgery.**—P. Gorse and A. Dupitch, discussing the various surgical procedures so far employed in lung tuberculosis, states that direct drainage of tuberculous cavities and pneumectomy have been uniformly unsuccessful. Chondrotomy or Freund’s operation is applicable only to incipient apical cases, and these can be cured through medical treatment alone. Friedreich’s thoracoplasty is a severe operation and has been abandoned by almost all. Artificial pneumothorax, on the other hand, has yielded remarkable results in grave forms of lung tuberculosis in which medical measures had failed. In serious cases following an acute course it is the only method now at hand to arrest for a time the progress of the disease to a fatal termination and even, in some cases, bring about temporary or permanent recovery.

**Splenectomy and Talma’s Operation in the Treatment of Splenomegaly in Association with Hepatic Cirrhosis in the Stage of Ascites.**—T. Tansini and G. Morone report that excellent results have been obtained in four cases of advancedBanti’s disease and one of malarial splenic enlargement with ascites by combining Talma’s operation (omentopexy) with splenectomy. The greater part of their paper is taken up with a discussion of chronic splenomegaly due to splenothrombosis and pylethrombosis, to which but little attention has so far been directed. In the form due to chronic splenic thrombophlebitis, of which they report a case in detail, the clinical and hematological manifestations may be the same as in primary forms of splenomegaly. The diagnosis is always difficult. Splenectomy is an effectual radical measure in the treatment. In combination with omentopexy it may also yield excellent results where hepatic cirrhosis coexists. The changes in the blood picture after operation are the same as those observed after splenectomy for other splenic affections, viz., the hemoglobin rises nearly to normal; the red cell count may exceed slightly the normal, then gradually return to the condition existing before intervention, and a slight leucocytosis, with pronounced eosinophilia, persists. Febrile complications of obscure causation may follow the operation, as in the case of other splenic disorders. In pylethrombotic splenomegaly, primary or secondary, medical treatment should alone be employed, three patients treated by splenectomy having succumbed.

**BRITISH MEDICAL JOURNAL.**

September 27, 1913.

**Reaction of the Blood Serum as an Aid to the Diagnosis of Cancer.**—W. D. Sturrock cites the observations of Moore and Wilson, who found that the serum of cancer patients showed a definite increase in alkalinity over the normal. Believing that such a finding might be of some clinical value, Sturrock has modified one of their methods so as to be applicable to clinical needs, and has made a number of observations on both cancerous and normal patients. Blood is collected in a serum tube, being drawn through an antitoxine needle. It is kept sterile and allowed to stand for twenty-four hours in a vertical position. It is then centrifuged to obtain clear serum. A series of dilutions of sulfuric acid are made, running from \( \frac{N}{7} \) to \( \frac{N}{4} \) and including the 4.5, 5.5, and 6.5 dilutions. For titration a few drops of a one per cent. alcoholic solution of dimethylamidazoebenzol are placed on a filter paper to be used as the indicator. A small quantity of distilled water is drawn into a capillary pipette, then a small drop of air, then serum is drawn up to a point marked by a thread about three centimetres up the tube, a second drop of air is admitted, and finally an amount of one of the dilutions of sulfuric acid is drawn up equal to the amount of serum used. The entire contents of the pipette are blown out onto a porcelain slab and mixed by aspiration. Finally the mixture is blown out onto the test paper. This process is carried out with ascending strengths of the acid until the test paper shows the first change of pink. The average alkalinity of normal blood is 0.170 N, and that of cancer patients’ blood (twenty-four cases) is 0.190 N. It would seem from Sturrock’s observations that a blood with an alkalinity of 0.200 N, or over, leads to the presumption that cancer is present, and in the author’s opinion it is sufficient to warrant an exploratory operation in doubtful cases. It is especially noteworthy that the high readings are most frequently found in the early cases, those in which the general metabolism is not seriously affected. The converse—that a low alkalinity is proof of absence of cancer—is not true.

**The Autoplastic Ovarian Graft and Its Clinical Value.**—Beckwith Whitehouse was compelled to remove both tubes and ovaries from a young woman on account of old pelvic septic inflammation. A portion of one ovary alone was still normal, but it could not be preserved in its normal position. This he cut into small pieces, each of which was implanted into the subperitoneal connective tissue, or into the rectus muscle. Care was taken not to remove the material from the body fluids before it was to be grafted. It was, therefore, allowed to lie free in Douglas’ pouch until ready for closing the wound. The grafts seemed to take and to live
for now more than ten months since operation, the patient has regular menstrual phenomena including bleeding from the uterus and headache. The author believes that this operation has a distinct field of usefulness. In cases of pelvic disease in young women where the appendages must be removed, but where the uterus can be preserved, such an operation would seem advisable in order to preserve the source of the ovarian hormones and to preserve the normal sexual functions in so far as possible. In severe cases of dysmenorrhea ovarian grafting may be found to relieve the condition without complete unsexing of the patient by oophorectomy, as now often practised.

Affections of the Heart in Childhood.—F. J. Poynton does not regard the elements of cardiac strain as material factors in the development of cardiac disease in childhood. He regards rheumatism as an infective process and as the greatest factor of all in the causation of heart diseases of childhood. Animal experiments have shown that the bacilli isolated from the vegetations in an acute fatal endocarditis are capable of causing vegetations on the heart valve of a rabbit in three days, along with definite myocardial changes. While most of the infections occur through the nasopharyngeal lymphatic tissues, the enucleation of the tonsils is not a certain preventive of such infection. Poynton’s views on the treatment of rheumatic endocarditis may be regarded as somewhat heretical. He does not regard the salicylates as definitely proved specifics, and thinks that delicate children do not do well under the large doses often employed. He no longer feels the mysterious dread of meat in the diet of rheumatics, for he regards the condition as one of bacterial infection. He is not convinced of the close relation between bad teeth and septic endocarditis. While he is not a blind opponent of the use of vaccines, he does not think it is justifiable to risk the giving of large doses of these in acute stages of the disease, and has seen acute pericarditis lighted up as a result of their administration.

—Carey Coombs is decidedly more definite in his statements than is Poynton, and agrees with him in many important details. He believes, with Poynton, that rheumatism is a streptococcal infection. The infective agent enters the body in most cases, if not in all, by way of the lymphoid tissues of the nose and throat. The organism reaches the heart through the arterial system, and the attack upon this organ is made simultaneously on all parts of its wall. The myocardium is injured in every case, and the mitral valve in most instances. The progress of the infective process is not steady but is marked by periods of complete quiescence, broken by phases of active disease. The histological picture of a mild recurrence differs from that of a severe attack in degree only. Each recurrence is due to the arrival of a fresh supply of microorganisms from without the heart by way of the blood stream. As the recurrences occur so close together, it is not probable that each is due to a fresh infection from without, but it seems that the streptococci are present in the body all the time, and only reach the circulation at intervals. The individual attack tends strongly toward recovery, and the danger lies in the tenacity of the organism rather than in its virulence. Treatment is of little avail in so far as the cure of the disease is concerned when once it has attacked the valves and the myocardium, and a certain amount of damage is done at each attack, which becomes permanent with the development of cicatricial tissue.

LANCET.
September 27, 1913.

Syphilis: Its Dangers to the Community, and the Question of State Control.—H. C. French expresses the following essential opinions on state control of venereal disease and prostitution, drawn from twenty years of practical experience in many countries. 1. Confidential medical notification of disease on prima facie evidence, and treatment in hospital for short periods in the early, active stages when the disease is most contagious. Such notification by medical men meets the difficulty encountered in the great source of syphilitic spread, clandestine prostitution, which is said to be the cause of five cases out of six. 2. Effectual control of public prostitution by adequate police measures for irreclaimable prostitutes. Such measures incalculably benefit both the individuals and the community, and cause a great reduction in the prevalence of venereal disease and a reduction in the number of prostitutes. 3. Soufèneurs, who act as middle men and live on the earnings of women, must be rigidly suppressed. 4. Protection of orphan children and of minors, with the suppression of street begging by children. No girl under twenty-one years of age should be allowed to live in a brothel in any capacity. 5. Loitering or solicitation in the streets, either by women, or by men acting in their behalf, should be rigidly suppressed. 6. Free voluntary dispensaries should be provided where clandestine prostitutes can secure treatment and be reclaimed. Such dispensaries should be open at hours which are suitable to the working class, preferably in the evening. 7. Disorderly persons should be removed from towns, and measures taken to prevent the return of evicted persons, and to prevent the harboring of diseased prostitutes in brothels. 8. Adequate control of diseased merchant seamen, who are a great source of the spread of venereal disease. 9. Control of persons who seek medical aid from druggists and pharmacists. 10. Circumcision of male infants and of all recruits who enter the army with phimosis; this markedly protects against the contraction of syphilis. 11. Punishment for concealing venereal disease, or for transmitting it knowingly to another. 12. The marriage of syphilities under ten years after the contracting of the disease should be discouraged by law. “Such measures may not completely deal with this difficult social problem, but they are the condensed experience of practical work as opposed to theoretical considerations. They are the bedrock on which an adequate superstructure can be laid. They do not conflict with public morality, but minimize disease, misery, and death.”

The Bacillus Lepra: Has It Been Cultivated?—Henry Fraser and William Fletcher believe that it has not. They base their belief upon the results of their own very extensive experiments using material obtained from thirty-two nonulcerating
cases of leprosy, with which they made 373 inoculations onto the various culture media. They ran the entire gamut of media and methods, and tried some new modifications. They used both the ordinary media and those which had been said to yield a growth of the bacillus. Their inoculations are not open to the contention that they did not introduce enough of the bacilli, for each specimen was examined microscopically and found to be most abundantly filled with the bacilli. Yet in no single instance were they able to discover any evidence of the growth of the bacillus, though in some cases the bacilli introduced seemed to remain alive and in about the same numbers as when the inoculation was made. They find that unless the greatest possible care be observed in the taking of the specimen for inoculation the cultures will be contaminated by one or more of a considerable variety of organisms.

The Pathology of the Condition Known as Parasyphilis.—As the result of prolonged study, James McIntosh and Paul Fildes discard the older views and offer a new one. After discussing the evidence for their view, they sum up by saying:

...it is clear that cerebrospinal syphilis is due to a reaction in the altered lymphovascular tissues of the meninges and vessels, and since it is thus focal the brain substance will be little involved. If, however, an exacerbation occurs in a nidus of spirochetes which has been left latent in the nerve tissues from a previous encephalitis, an excessive reaction will follow in these tissues, and will lead to degeneration of the nerve cells (parasyphilis). Thus in our view cerebrospinal syphilis is due to a tertiary hyperallergic reaction in the vascular tissues, while parasyphilis is due to a tertiary hyperallergic reaction in the nerve tissues and accompanying interstitial tissues (neuroglia).

This view, therefore, admits no essential difference between the lesions of encephalitis of the secondary period and encephalitis of the tertiary—dementia paralytica—except in the greater susceptibility of the tissues in the latter.

The Treatment of Umbilical Hernia in Children.—John Fraser makes three equidistant radial incisions through the skin at the base of the protrusion, after complete reduction of all the hernial contents. By blunt dissection the skin is raised free from the underlying fascia all the way around the base of the hernia, and through this subcuticular channel is passed a strong elastic ligature, both ends of which are brought out at the lower opening. This is drawn firmly around the neck of the tissue into which the sac protruded, and is fastened by binding with a silk ligature. A dry, sterile dressing is placed over the wound and it is left for six days when the elastic ligature is removed by cutting the silk knot. The opening in the skin closes quickly and the hernia is cured. Such treatment has given most satisfactory results in twenty-one cases. It is not applicable to patients under six months of age, nor to those in which the abdominal opening is large enough to admit freely the tip of the little finger.

JOURNAL OF TROPICAL MEDICINE AND HYGIENE. August 15, 1913.

Relapses in Malaria.—J. P. Bates lays stress on the frequency with which relapses follow the primary invasion in malaria, having had under ob-

ervation some cases in which the possibility of re-infection could be eliminated and the various relapses closely watched and recorded. The relapses are most troublesome and persistent among children, always active and impatient of control, and among adults whose duties force them out again too quickly after the subsidence of the fever. In these, relapses occur at short intervals such as two or three weeks, up to from one to three months. The intervals bear some relation to the thoroughness of treatment. Discussing the various hypotheses advanced to account for relapse in malaria—parthenogenesis, intracorporeal conjugation, and sexual development in the human host, Bates shows that the connection of these with relapse is purely conjectural, and asserts his belief, supported by the well known facts of latency in malaria, that a few malarial parasites may survive the effects of quinine and development in asexual cycles continue for an indefinite period. Immunity, combined with treatment, finally limits the relapses. The time necessary for the development of immunity to malaria is not known, but one may assume from experience that it is not more than two or three years in most instances. The immunity may later be lost altogether.

BOSTON MEDICAL AND SURGICAL JOURNAL. October 2, 1913.

Indications for the Relative Values of Tonsilotomy and Tonsillectomy.—J. L. Goodale says that it has not been demonstrated that complete removal of the tonsils is followed by harmful effects upon the general system. Tonsillectomy usually involves less trauma than does tonsillectomy, but in the latter the method of removal is of primary importance, a sharp dissection down to the tonsillar artery, with snaring of the vessels giving the least amount of inflammatory reaction. Of the two operations tonsillectomy shows a larger percentage of septic complications, due both to the greater trauma and the relatively larger number of septic conditions where of late years an operation is undertaken. The relative frequency of postoperative hemorrhage is not definitely established, but this is no longer a serious complication if dependent on local causes. While gross deformities of the parts involved are not likely to follow tonsillectomy, yet cicatricial occlusion of the larval orifices is frequent and may lead to an intensification of the original chronic inflammation. Tonsillectomy in unskilled hands may be followed by marked and injurious distortion, but with good technic should have no other alteration than an approximation and occasionally a partial fusion of the pillars. The indications for operation should be determined by the pathological changes in the tonsils, which are actually a detriment to the individual. Simple hyperplasia, if obstructive or following catarrhal conditions, and if persistent, may be sufficiently treated by a tonsillectomy, especially in children. The systemic effects of chronic tonsillitis may be increased by a tonsillectomy, so here complete removal is preferable, although mild cases of chronic inflammation may be sufficiently relieved by appropriate treatment without excision. Infection of the fauces by virulent microorganisms may not be prevented by removal of the tonsils. Recurrent local infections, or gen-
eral infections originating in the tonsils, require tonsillectomy at the earliest favorable moment; tonsillectomy may be expected to prove inadequate. Re- current acute catarrhal infections of the throat require complete removal of the tonsils if these show chronic inflammation, though immunity against subsequent attacks is not necessarily secured. Local tuberculosis of the tonsil requires complete removal. The tonsils should not be excised in young children with adenoids that require removal unless they are demonstrably causing injury, or favoring attacks of acute middle ear inflammation. If an impairment of the speaking voice is dependent upon tonsillar disturbances, these may be corrected according to the principles already given, and if a tonsillectomy is indicated, it may be performed without anxiety with proper technic. A slight alteration in the tension of the palatal muscles may influence the voice of singers either favorably or unfavorably. In the case of beginners with harmful alterations in the tonsils a partial or a complete removal may usually be done, if the local or general welfare of the patient demands it. With increasing length of singing experience a correspondingly conservative attitude should be maintained, particularly in respect to truly fine voices.

Observations on a Series of Ninety-eight Consecutive Operations for Chronic Appendicitis.—E. A. Codman presents an energetic and logical argument to prove that a routine appendectomy should be performed on every child.

Studies in Auscultatory Blood Pressure Phenomena: The Clinical Determination of Diastolic Pressure,—L. M. Warfield finds that it may be affirmed that there is both clinical and experimental evidence to prove that the point at which diastolic pressure should be read, when using the dial instrument, is at the point where the fling of the lever during the gradual lowering of pressure suddenly becomes less, or, better, where the clear sharp third tone suddenly becomes dulled.

The Responsibility of the Dentist and the Physician in Regard to Mouth Infections and Their Relation to Constitutional Effects.—T. B. Hartzelle says that an infected mouth, with its enormous surface for bacterial growth, may produce four distinct pathological effects: 1. That produced by the dissemination of bacteria through the medium of lymphatic drainage; 2. that produced by bacteria through the open bloodvessels; 3. that damage sustained by the individual through the change in the chemistry of digestion caused by bacterial poisons; 4. that produced by a general bacteremia which not infrequently is a direct result of the dissemination of bacteria in the blood. He would not think of contending that all diseases may be traced to mouth infections, but he has observed many cases of general infection of different characters which have been found due to such infections. Statistics gathered by him show that there is about one case in ten in which severe constitutional lesions occur (lesions which are usually overlooked both by physician and dentist) traceable to the mouth. He then gives the summary of findings in 1,020 cases of mouth infection.

The Value of Sanitation as Applied to Railway and Other Large Corporations.—M. C. Thrush, as the result of his studies, makes the following recommendations as applicable to all large railway corporations: 1. All such corporations should have a department of health and sanitation, which should direct and control all matters pertaining to the medical welfare of both its employees and the public. 2. There should be an expert sanitarian in charge of this department who should be a doctor of medicine and who should have the same authority in this department which the general manager has in the operating department of the road. 3. He should work directly in conjunction with the general manager, both being under the supervision of the president of the company. 4. There should be twelve department superintendents, each of whom should have direct supervision of one of the following special departments: Relief; efficiency examination of employees; sanitary inspection of buildings; inspection of road beds; inspection of the rolling stock; inspection of new construction; first aid to the injured; supervision of railway surgeons; medicolegal department; supervision of hospitals and dispensaries; purchasing of medical and surgical supplies; department of statistics. These should be controlled and managed by the medical director. 5. The director's office should be located at the general headquarters of the company. 6. The adoption of this plan would result in more efficient service with less expenditure, and produce a condition of greater safety and protection to the traveling public.

The Employment of Carmin in Gastrointestinal Diagnosis.—Seymour Basch finds that in the carmin test we have a simple, safe, reliable, and convenient means for the demarcation of stools,
the estimation of gastrointestinal motility and patency, the detection of fistulous communications of the alimentary canal with the exterior or with other hollow organs, the location of the distal end of a duodenal tube, and the differentiation, with its aid, between esophageal diverticulum and dilatation.

**A Neosalvarsan Fatality.**—M. E. Hagerty reports the death from acute arsenic poisoning of a patient twenty-nine years old after a dose of 0.6 gramme of neosalvarsan, given intravenously. Previously he had had but one other dose of the drug, and this (of the same character) was some six weeks before. The author states that while this is the first fatality occurring to him in over 600 injections of salvarsan, it is the seventh death to his knowledge resulting from salvarsan in the city of St. Louis. The case now reported, he says, is perhaps one of the most striking examples of what may happen following the injection of salvarsan, even under the most favorable circumstances, that is, in one who was not suffering from any serious organic lesion; and it is especially significant owing to its correspondence with a report of Wechselmann, and also that of Homer F. Swift, of three almost identical cases.

**MEDICAL RECORD.**

October 4, 1915.

**Colliculitis, or Disease of the Verumontanum.**—In many textbooks not yet considered old, A. L. Wolbarsht says, the verumontanum or colliculus is mentioned as a more or less vague and indefinite ridge on the floor of the posterior urethra; little is said about its physiology, except that it is thought to be the seat of sexual feeling, and about its histology and pathology, practically nothing. With the development and perfection of the posterior urethroscope, however, all this has been changed. With the newer instruments the colliculus is seen as a distinct projection from the floor of the urethra, which in general may be said to resemble an enlarged clitoris. As a rule, the uricle is situated at its summit, being flanked on either side by the ejaculatory ducts. Our knowledge of its pathology is not yet sufficient to cover all the ills to which the colliculus may be subject, but it may safely be stated that its most common pathological condition is the inflammatory process following or coincident with a gonococcus infection of the deep urethra and prostate. Hence we must not be surprised to find inflammatory conditions of the organ in cases of premature ejaculation, sexual impotence, sterility, and the male neuroses. Inflammatio of the colliculus is not always of gonococcus origin, however, as any persistent irritation involving the sexual function, such as excessive masturbation, may be responsible for the inflammatory process. Treatment consists almost entirely in the application of silver nitrate (preferably in ten per cent. solution) through the posterior urethroscope. Other applications mentioned are diluted tincture of iodine, the galvanocautery, and the Oudin high frequency current; the last named being particularly indicated in the presence of cystic and papillomatous growths or of dilated ducts and glands.

**Venereal Prophylaxis, Past and Present.**—R. A. Bachman reviews the history of venereal prophylaxis and gives some account of the results, particularly in the American army and navy. He expresses the opinion that tube prophylaxis is the only system which can ever give any marked beneficial results because it is the only one that provides for immediate application, without which no success can be expected. The only tube which has received any official recognition in the navy is the one he devised. In this the ointment used is Metchnikoff's 33.3 per cent. calomel salve modified by the addition of one per cent. tricresol. The present Maus tube, used in the army, contains three per cent. phenol, three per cent. camphor, twenty-five per cent. anhydrous wool fat, and forty-four per cent. lard ointment.

**Antityphoid Vaccination.**—A. H. Doty states that his intention is not to minimize the value of this form of treatment within reasonable limits and in the hands of those properly equipped to administer it, but rather to inquire into its range of usefulness and to suggest that we carefully consider its defects, as well as the protection it extends. Having pointed out the differences between this and vaccination for the prevention of smallpox, he says that the protection of soldiers and sailors against infectious disease is a responsibility which very properly rests with the medical officer in charge; furthermore these men are employed for the protection of the public, and must be prepared at any moment to deal with emergencies. In connection with this duty they are frequently transferred from one place to another, and may often be exposed to very bad sanitary conditions; therefore unusual or more extended means of safeguarding their health is justifiable. There are other emergencies in connection with outbreaks or anticipated outbreaks of typhoid fever, and also other conditions, where the vaccine may be useful. He does not believe its employment advisable, however, as a preventive measure in hospitals, stating that if it is depended upon, in some way relaxation will take place in the enforcement of the sanitary measures which are imperative in the care of typhoid. During the past year the public in various parts of the country, and particularly persons about to travel, have been officially advised to secure the benefits of the antityphoid vaccine, but he does not think a general recommendation of this kind proper or wise. Nor does he accept the statement that this means of prevention involves no risk, for it is generally conceded that any acute infectious or organic disease, or impaired health, contraindicates the use of this measure. Hence, those in charge of the public health should deal in the most cautious and conservative way in approving or recommending a serum or vaccine for general use. Doctor Doty believes that those who will give this subject careful consideration will be convinced that the employment of antityphoid vaccine as a preventive measure should be strictly confined to conditions or emergencies where it is deemed justifiable to carry out special means of protection. Under these circumstances unpleasant results may be avoided, and the public mind will not be disturbed, or its faith weakened in modern sanitary methods in which its cooperation is so urgently needed and which are so essential to the preservation of health.
Extract of the Pituitary Body of the Ox in the Treatment of Rheumatic Arthritis.—Charlton Wallace and F. S. Child present a preliminary report on this use of pituitrin, giving the histories of ten cases, five of which were hospital cases in children and five in adults in private practice. All the patients showed improvement in the general condition, in the pains, swellings, and motions of the joints affected, and in the effect on the bowels. The blood pressure was elevated throughout the treatment, and had a tendency to remain so. There was a slight, irregular rise in temperature during the first week or ten days. In one of the children the prognosis, under the treatment, was changed from fatal to favorable. The adult patients were slightly nauseated and suffered from head symptoms, such as giddiness, lightness, and headache. Under the aseptic precautions employed the patients gave no sign of needle infection, nor did they have much pain from the intramuscular injections. In some instances as many as twenty-five injections were given. The preparation of the material used is described.

JOURNAL OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

W. E. Casselberry believes that the condition classed as nasopharyngitis, but common, referred to as postnasal catarrh, is due to an extent not yet realized to infection of the sphenoïd sinus, together usually with implication of the postethmoid cells. In point of frequency, however, it is not that grade of infection already known as empyema or suppuration of the sphenoïd sinus whose product is typical pus, but it is the attenuated type in which the discharge appears as variously modified purulent products. The secretion issuing from the sphenoïd sinus may vary from pus to mucopus or it may be viscid mucilaginous or sometimes a fetid substance, which, when copious, forms into long,ropy strings and blocks the nasal passage, defying ordinary means of expulsion. The headaches produced may be indicated by pain at one or more of five points, i.e., the back of the head, the top of the head, the eye, the ear, and the upper jaw. About one third of the author's cases of supplicative sphenoïditis were asthmatic subjects, and the degree of benefit derivable from the surgical treatment of the nasal conditions was found to be proportionate to the thoroughness of the operation.

Proceedings of Societies.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting held on April 9, 1915.

The President, Dr. Charles A. E. CooMAn, in the Chair.

Case of Congenital Diffused Lipoma of the Foot and Leg.—Dr. J. Oraranee Rugh exhibited a patient and discussed the symptoms and diagnosis of this rare condition and reviewed the treatment. The patient was a girl, aged six and one half years, with good family history. At birth there was marked enlargement of the second and third toes of the right foot with a mass of fat underneath the front portion. There was no pain nor tenderness, and the skin was normal in color and consistency. At six months two toes were removed without difficulty. At fifteen months a large mass of fat was dissected from under surface of the foot. Scarls- tina developed in four days and part of flaps sloughed but healing took place eventually in two months. At twenty months enlargement of calf began of the same type as in foot. X ray taken at six years showed no enlargement of bony structures. Specimen taken for examination from the foot mass showed a typical lipoma without evidence of fibromatosis. Removal of masses would be attempted but failure with subsequent enlargement or recurrence of the mass would call for amputation above the margin of the upper mass.

The Nervous Symptoms of Pelvic Disease.—Dr. F. X. CERCE remarked that with the coexistence of pelvic disease and neurasthenia the pelvic symptoms might be more readily recognized by the patient and therefore became more prominent, because in neurasthenia the reaction of the nervous system to abnormal or pathological impressions was greatly increased. In hysteria incautious remarks and injudicious statements by a physician might be very injurious. The suggestion of an operative procedure was accepted readily and sometimes a long series of operations had thus its beginning. It was hardly necessary to state that no relation existed between pelvic disease, epilepsy, chorea, and other nervous diseases. The nervous symptoms which could be truthfully ascribed to pelvic disease were pain in the pelvis, pain referred to the back, to the top of the head, to the hips, and to the thighs, with associated signs of general ill health. These symptoms could be dignified by the name of a nervous disorder, but were merely part of the symptom group of the pelvic disease. Operation should be for the pelvic condition itself and not for the relief of an incidental nervous symptom. Operation was done just as we set a broken leg in an insane man, not because he was insane, but because the leg is broken. It was important in considering operations upon neurasthenics to bear in mind that these patients were excessively sensitive to nervous shock. In such cases the operation, if not urgently indicated, might with advantage be preceded by a period of rest.

A Modification to Obviate the Defects of the Newer Methods of Repairing the Pelvic Floor.—Dr. Barton COOKE Hirst stated that injuries of the birth canal constituted more than half of all the diseases of women. All over the world there was a tendency to discard the older operations on the perineum and posterior vaginal walls, such as Hegar's and Emmet's, and to prefer the transverse incision with dissection of the rectovaginal septum and to expose the levators and deep transverse perineal muscle, a method developed from Lawson Tait's original technic. The reasons for this unanimity of opinion would appear to be the failure in the older operations to expose and directly unite the muscles injured in parturition; the failure to restore to the pelvic floor the support and contour it possessed before childbirth. The newer technic, however, was not yet perfected. With a clear
The President, Dr. CHARLES A. E. GODMAN, in the Chair.

Marked Arthritis Deformans Greatly Improved by Physical Means.—Dr. A. B. HIRSCH remarked that the patient shown had been through the usual course of treatment and had done the round of the different spas without benefit. She was very much bent and was obliged to use a cane in walking. The treatment had been by electrical methods alone, the static and high frequency coil currents. Bacterial infection was excluded by the laboratory examinations, and the condition resolved itself into one of long continued absorption of toxins from roots of teeth. The case showed the value of long continued physical treatment in those cases otherwise almost impossible of relief.

A Modern Extraperitoneal Cesarean Section and the Best Technic for Its Performance.—Dr. BARTON COOKE HIRST illustrated the operation by a series of drawings. An incision was made below the umbilicus, and large enough to extract the child's head. After making the incisions in the two layers of the peritoneum they were sewed together, which immediately closed the peritoneal cavity, making the operation extraperitoneal. Then followed the incision in the uterine wall made in the ordinary way, and the extraction of the child's head with forceps. The lower uterine segment was sewed with double catgut and the abdominal wall closed in the usual way. It had been found to increase hemorrhage if the placenta was delivered from the uterine wound. It was rather better to clip the cord off, drop it into the uterus, sew up the uterus, and deliver as usual. If the woman was not in labor it was necessary to extract the placenta through the uterine wound.

In the discussion that followed Dr. JOHN B. DEAVER said that the fact that Doctor Hirst was one of the two who had done this operation in this country and that he had done nine of the ten operations performed spoke for itself from the standpoint of experience. It always appealed to him as good surgery to deal with the condition extraperitoneally. By Doctor Hirst's technic there might, it seemed to him, be perhaps a little greater danger to the life of the child. Dr. GEORGE M. BOYD observed that the lowered mortality in Cesarean section had led some of our American surgeons to resort to the extraperitoneal operation. He believed that the Cesarean section was a child saving operation. Dr. WILLIAM R. NICHOLSON had witnessed two thirds of the operations which Doctor Hirst had performed by this technic. Within five years, he believed, there would be a larger percentage of men doing this operation in selected cases. Statistics did not prove that the true extraperitoneal technic was any better than the transperitoneal method. Doctor Hirst had used a continuous stitch which seemed to be absolutely tight and left a space of eight or ten cm. long and three to five cm. wide. The true extraperitoneal method had not a point of any advantage. If the case was septic the patient would die just as readily no matter which technic was employed. The general obstetric operator who had not the facilities for becoming especially expert in technic would do better to adhere to the intraperitoneal route. Dr. E. E. MONTGOMERY thought that one of the diagrams seemed to show that Doctor Hirst opened the peritoneum and made his operation extraperitoneal by closing up the peritoneum on either side. Without question this was an operation which was preferable to the method known as the pure extraperitoneal. Every operation must be judged by its mortality, morbidity, and the conditions in the event of subsequent pregnancy. Statistics indicated that there was not great demand for an extraperitoneal operation in the ordinary case where there was no reason to suspect infection. The section of the peritoneum in Doctor Hirst's method laid bare the uterus and he would like to know what influence this had upon the action of the bladder. Dr. EDWARD P. DAVIS remarked that Doctor Hirst's description of this technic was an interesting contribution, but the operation was not the extraperitoneal section that he had seen. He welcomed, however, most heartily this method of delivery through a peritoneal fistula. He should like to know what Doctor Hirst would do in cases of sepsis. Personally he should not like to employ this method in the presence of hemorrhage or in cases in which he had doubts as to the condition of the uterine muscle. Dr. JONATHAN LARKIN FORWOOD stated that he had done Cesarean section forty-two times in the Chester Hospital in a period of ten years. His operations had been intraperitoneal. A vertical incision was made through the abdominal walls in the usual way. He formerly made the incision large enough to lift the uterus out and then opened the uterine walls and delivered. Now he operated by cutting through the anterior surface of the uterus an opening large enough only to deliver the child. Hemorrhage had been controlled by the uterine arteries being held by an assistant placing a hand on either side. He did not cut low down in the lower segment for he believed much of the hemorrhage came from the fundus of the uterus. When the uterus had been sewed up ergot was given hypodermically. In three of the forty-two cases instruments had been applied and there was infection. He operated on one
Letters to the Editor.

THE ETERNAL MEDICAL VERITY.

173 Lexington Avenue.
New York, October 4, 1913.

To the Editor:

The brilliant article of Dr. W. B. Konkle in to-day's issue of your esteemed JOURNAL is of far reaching importance, for such writing certainly induce us to keep in view the precious benefits of classical civilization and above all to study the history of medicine. In view of the materialistic tendency of our time it is well to be reminded that there have existed men who paid little attention to those things which are admired above all others at present, who devoted their lives to ideals and to science. When we familiarize ourselves with medical history we imitate Jupiter, who took every year the wonderful bath which rejuvenated her. Without studying the history of medicine, without this spiritual revival, without reading of the great physicians of classical antiquity we are in danger of bemoning ourselves. The study of the history of medicine will relieve us from the monotonous, enthusiastic laudation, and nothing but laudation, of modern medicine, which we are accustomed to hear on all sides in the presidential addresses, at our medical congresses and societies.

Achilles Rose, M. D.

Book Reviews.

This admirable and scholarly book is written by army surgeons from statistics compiled from army sources and therefore more dependable than the statistics of clinics and dispensaries. Not as reliable as statistics compiled from private practice. The first chapters deal with the histories of syphilis and the methods of prevention used in various European armies. In commenting upon a reduction in the daily inefficiency caused by syphilis the authors suggest as an explanation that "syphilis is probably contracted in most cases from the degraded class of prostitutes with which an ordinary self respecting man does not consort when sober." I think it is generally believed, however, that practically all prostitutes contract both syphilis and gonorrhea in the first two years of their prostitution. The chapters on pathology and the serum diagnosis of syphilis are exhaustive. The authors note the interesting fact that by administering a provocative injection of salvarsan a negative Wassermann reaction may be changed to a positive one. A modified reverse of this which the authors make no mention of is the fact that salvarsan injections may be followed by a negative Wassermann reaction in spite of the fact that the patient may be having active symptoms. If the case be still further untreated this negative Wassermann will of course change to a positive. The chapters on salvarsan and neosalvarsan are the best we have seen in any textbook. It is generally believed that neosalvarsan is not as effective as salvarsan but the authors apparently do not subscribe to this belief although most of their work has been with salvarsan. An interesting table of mercury equivalents for use in the army is given: One injection of one and one half grains of metallic mercury is equivalent to three injections of a soluble salt containing one fifth of a grain in each injection or to seven daily inunctions, using twenty grains of mercury daily, or to twenty-one pills each containing two grains of hydrargyrum cum creta. If the Wassermann reaction is a reliable guide in estimating the values of different kinds of antisyphilitic treatment, then our opinion in any way, or in any quantity, do not seem as effective as inunctions or injections of the insoluble mercurials. The complement fixation test is to gonorrhea what the Wassermann test is to syphilis, and yet the authors entirely neglect mentioning it in their "Cures" for gonorrhea. In the appendix there are a number of interesting formulae, histories, etc.

A Practical Manual of Venereal and Generative Diseases. Spermatorrhea, Impotence, and Sterility in Both Sexes. By Gerald Dalton, Late Assistant Surgeon to St. Francis's Hospital and Lecturer to the Nursing Staff, Assistant to the Skin Department, Charing Cross Hospital, etc. New York: William Wood & Co. 1913. Pp. viii-156. (Price, $1.75.)

The first chapters of this book on gonorrhea (male and female) and syphilis are too incomplete to be seriously reviewed. In the chapters on syphils comprising twenty-two pages the following pages are found, page 71: "Directly one or more of the secondary symptoms appear, internal administration of mercury must be commenced." This is antediluvian. Page 73: "A third method is by intramuscular injections, or more strictly speaking, injection into the subcutaneous tissues." We know they result if an intramuscular injection accidentally becomes a subcutaneous one. He dismisses salvarsan and the Wassermann reaction after four and one half pages. He dismisses the former on the fact that it mainly interested in reporting the deaths therefrom. The chapters on generative diseases, notwithstanding one has difficulty in knowing what is meant by the title, are complete and good.

This bulletin, in its presentation of conditions along a single one of many important waterways in this country, calls attention to what is almost a criminal carelessness concerning the disposal of sewage. Although the fever may not be completely eliminated, on account of the presence of the typhoid carrier, it can, and should be, greatly diminished. That the water supply is the great source of infection cannot be denied, and when we consider the conditions as shown in this report it seems surprising that there is not more typhoid. This bulletin and No. 83 as well should be obtained and carefully perused.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 8, 1913:

Nydegger, J. A., Surgeon. Directed, in returning to station from Bartholomew County, Ind., to stop at Indianapolis, Ind., for conference with the State Board of Health.

Pettus, W. J., Assistant Surgeon General. Relieved from duty at the Bureau of Medicine and Surgery, Washington, D. C., effective on October 15th, and directed to report to the director of the Hygienic Laboratory for special instruction.

Porter, J. V., Quarantine Inspector. Detailed to represent the Service at the meeting of the Southern Medical Society, at Lexington, Ky., November 18 to 20, 1913.

Ruffo, J. S., Assistant Surgeon. Granted one month's leave of absence from September 16, 1913, on account of sickness.

Schereschewsky, J. W., Surgeon. Directed at the request of the chairman to attend the meeting of the Committee on Rural Nursing of the American Red Cross Association, to be held at New York, N. Y., October 22, 1913.

Smith, Howard F., Assistant Surgeon. Directed to report to the chief quarantine officer, Manila, P. I., for duty.

Stiles, C. W., Professor. Directed, at the request of the State health authorities, to confer with local health boards and present lectures relative to measures necessary to improve sanitary conditions at various places in North Carolina.

Von Ezdorf, R. H., Surgeon. Directed to proceed via Raleigh to points within the State of North Carolina, for the collection of data relative to the incidence of malaria and the means necessary to its control.

Weldon, L. O., Assistant Surgeon. Directed to report to the medical officer in charge of the Marine Hospital, Baltimore, Md., for duty and assignment to quarters.

Appointments:

Dr. Howard F. Smith and Dr. Lon O. Weldon commissioned assistant surgeons in the United States Public Health Service.

Official News:

United States Army Intelligence:

Official list of changes in the stations and duties of officers in the Medical Corps of the United States Army for the week ending October 11, 1913:

Crum, Wayne H., Captain, Medical Corps. Granted leave of absence for three months, effective on arrival in the United States.

Culler, Robert M., Captain, Medical Corps. Leave of absence hereafter granted is extended one month, effective on October 12, 1913.

Brown, —. First Lieutenant, Medical Reserve Corps. Granted leave of absence for three months, to take effect about January 1, 1914.

Gilchrist, Harry L., Major, Medical Corps. Ordered to proceed to Chicago, Ill., for duty pertaining to the convention of the National Guard Association, to be held at that place on October 6, 7 and 8, 1913, and on completion of this duty to return to proper station.

Huntington, Philip W., Captain, Medical Corps. Granted leave of absence for one month, effective on about October 12, 1913.

McCaw, Walter D., Colonel, Medical Corps. Granted leave of absence from January 1, 1914, to April 20, 1914.

Stayer, M. C., Captain, Medical Corps. Ordered to Fort Porter for temporary duty on return to Madison Barracks of Major Perry L. Boyer, Medical Corps.

Walkup, J. O., First Lieutenant, Medical Corps. Ordered to Albuquerque, N. M., to read a paper before the New Mexico Medical Society, without expense to the government.

Whitmore, E. R., Major, Medical Corps. Joined the Army Medical School, Washington, D. C., on October 2d.

Worthington, J. A., Captain, Medical Corps. Granted three months' leave of absence, with permission to apply for an extension of one month.

Births, Marriages, and Deaths.

Married.

Cronin—Potter.—In Rye, N. Y., on Saturday, October 4th, Dr. Eugene J. Cronin, of Richmond Hill, and Miss Marie Blanche Potter. Jones—Milliken.—In Old Orchard, Me., on Monday, September 29th, Dr. Arthur Leon Jones and Miss Cora Lillian Milliken.

Whitmore—Christians.—In Denver, Colo., on the 1st day of October, Dr. George W. Newell, of Burlington, Wis., and Miss Corona Christiansen.

Torbert—Townsend.—In Cohasset, Mass., on Saturday, October 4th, Dr. James R. Torbert, of Boston, and Miss Elizabeth Townsend.

Died.

Arnold.—In Omaha, Nebr., on Thursday, October 2d, Dr. William Arnold, aged ninety-four years.

Baker.—In Herrin, Ill., on Thursday, October 2d, Dr. James G. Baker, aged forty-three years.

Bradley.—In Cedar Rapids, Ia., on Thursday, October 2d, Dr. William John Bradley, aged forty-seven years.

In Cleveland, Ohio, on Sunday, September 28th, Dr. George Summers Brown, of Birmingham, Ala., aged fifty-four years.

Hanson.—In Kenora, Ontario, on Tuesday, September 30th, Dr. Thomas H. Hanson, aged sixty-seven years.

Hoskinson.—In Gite City, Va., on Friday, September 26th, Dr. Lucian Beauregard Horton, aged fifty-two years.

Martin.—In Chicago, on Monday, September 29th, Dr. Hiram M. Martin, aged fifty-one years, and Miss Bertha Huntington, W. Va., on Friday, September 26th, Dr. A. H. Moore.

Newman.—In Penn Yan, N. Y., on Tuesday, October 7th, Dr. Omar E. Newman, aged fifty-five years.

Semple.—In St. Louis, Mo., on Friday, October 3d, Dr. Nathaniel M. Semple, aged thirty-seven years.

Stone.—In Indianapolis, Ind., on Friday, October 3d, Dr. Richard F. Stone.
THE LEGAL RESPONSIBILITY OF THE
SURGEON AND PRACTITIONER WHICH
THE USE OF THE X RAY
INvolves.*

By Ellsworth Eliot, Jr., M. D.,
New York.

In December, 1912, an experienced surgeon was
the defendant of a malpractice suit in which the
plaintiff recovered a verdict of over $11,000, on the
ground that the care of a simple fracture of the
lower part of the shaft of the femur, the result of an
automobile accident, had not received due and pro-
per attention. Four weeks after the accident the pa-
tient was seen in consultation by the writer and at a
considerably later period, in fact after a plating
operation by another surgeon, the patient was ex-
amined by the late Doctor Bristow. To us both,
subsequently associated in the defense of the action
in court, the importance of the case and the fact
that such a verdict, if sustained on appeal, would
make the physician or surgeon hesitate to under-
take the treatment of cases of this character, seemed
to warrant the presentation of its chief surgical
and legal features in the hope that this association
might take some action that would, in a measure at
least, protect the surgeon in future from unwar-
rantable suits of this character.

For this task Doctor Bristow kindly volunteered
and had prepared or was preparing a paper with
the title already cited when his unexpected and
most unfortunate death occurred. The importance
of the matter was such, however, that notwithstanding
the short notice, the writer was impelled to take
Doctor Bristow’s place in order that the question
might be presented to this association for discussion
without further delay.

The testimony showed that after the accident the
patient was conveyed to the nearest suburban hos-
pital in an ambulance, the fractured thigh having
been placed in temporary splints; that, at the end of
forty-eight hours after the shock had subsided,
the fracture was reduced by the defendant under a
general anesthetic and placed in a Buck’s extension
apparatus; that, at the end of the fourth week the
writer found the fragments imbedded in abundant
callus with no sign of either axial or angular de-
formity and with a shortening that did not exceed
one half an inch; that, near the end of the fifth
week, the union being sufficiently advanced to per-
mit of active rotation of the thigh, and no false
point of motion being elicited, the leg was put in a
plaster of Paris splint. The patient was then gradu-
ally allowed out of bed on crutches with adequate
support to the thigh and with strict injunctions to
bear no weight on the affected side, a nurse being
in constant attendance. At that time the shortening
did not exceed one half an inch.

From this time until her discharge from the hos-
pital, nine weeks after the accident, the testimony
was uneventful with the exception of one fact. At
the eighth week the plaintiff declared that a slight
slipping of the crutch caused her to lose her balance
and that although the nurse prevented a fall, the
patient involuntarily placed a slight amount of
weight on the affected side. The resultant pain was
so slight and of such short duration that the inci-
dent was not reported to the defendant by either
the nurse or the patient. In addition, the testimony
of the defendant showed that, contrary to his strict
injunction, the patient, at about this same time, had
made an effort to get out of bed unaided by the
nurse and in her absence and had felt a severe pain
at the point of fracture. It was on the following
day when the defendant, on measuring the thigh,
found a sudden increase in the shortening to almost
one inch, that, in answer to his question, the patient
reported this incident. Notwithstanding this sud-
len increase in the shortening the surgeon found
no false point of motion and concluded that there
had been some displacement of the fragments with-
out actual recurrence of the fracture. In the course
of the trial the conversation cited above was in-
dignantly denied by the plaintiff.

At the end of the ninth week and at her own ur-
genent and often repeated request, the patient was
discharged from the hospital and referred to her
own family physician in New York, with strict in-
junction to bear no weight on the affected side un-
til four weeks later or until the expiration of the
thirteenth week after the accident.

The family physician testified that on several vis-
its for minor ailments before the expiration of this
time, he had examined the fractured thigh and had
noticed some irregularity but no false point of mo-
tion. He also testified that he was present, when,
three weeks after leaving the hospital, patient made
an effort to bear the weight of the body on the af-
fected side and experienced such terrible pain at the
point of fracture that the experiment was not re-
peated. An x ray, taken four weeks later or sixteen
weeks after the accident had occurred, showed an

*Read at a meeting of the American Surgical Association held
on May 6, 1913.

Copyright, 1913, by A. R. Elliott Publishing Company.
old oblique fracture of the lower end of the shaft of the femur. The line of fracture made an angle of about twenty degrees with the shaft, and although in the anteroposterior plane the alignment was perfect, in the lateral plane the fragments appeared displaced to such an extent that the posterior aspect of the upper appeared to be in touch with the anterior aspect of the lower fragment. The fragment seemed firmly united with callus, there was no false point of motion, and the shortening did not exceed one inch.

Without the knowledge of the defendant a third surgeon saw the plaintiff in consultation four and one half months after the accident and advised an operation in which the fragments were exposed, their ends freshened by the removal of five eighths of an inch from each fragment and after alignment they were secured in the usual way by plates. An x ray, after union had taken place, showed some angular deviation notwithstanding the plates which, in the opinion of the plaintiff's physician, accounted for at least one quarter of an inch of the final shortening. At this stage the patient had been examined by Doctor Bristow and his testimony as well as that of the plaintiff's physician showed that the final shortening did not exceed two inches.

The removal of five eighths of an inch from either fragment together with the one quarter of an inch additional shortening due to the final angular deviation proved conclusively that prior to the operation the shortening could not possibly have exceeded one inch.

It was further shown by the testimony that, three weeks after the accident, at the suggestion of the defendant, an effort was made to secure an x ray with the hospital machine, but the result was unsatisfactory as the machine proved to be out of order, notwithstanding an attempt was made to put it in repair. It was also shown that several months would be required before the machine could have been placed in serviceable condition. The defendant was in no way held responsible for this failure as the machine was the property of the hospital.

No further attempt was therefore made to utilize the hospital apparatus and no suggestion was made by either the defendant or the plaintiff to call an x ray expert from New York. It was in lieu of an x ray that a consultation was suggested by the defendant and accepted by the plaintiff. In the course of the trial the medical testimony of the plaintiff admitted that the treatment as conducted by the defendant was a proper and recognized form of treatment and that the failure of the defendant to suggest the calling of an x ray expert constituted the sole basis for the charge of neglect.

In his charge to the jury the judge called attention especially to the fact that the defendant had failed to suggest the taking of an x ray after the failure of the hospital apparatus by a specialist from New York (twenty miles distant) and, in the opinion of the defendant's counsel, it was the special prominence given this fact that led to the unfortunate verdict.

The first question suggested is as follows: With firm union between the fragments of a broken shaft of the femur and with a shortening of an inch or less, is an operation indicated because on the first attempt to bear the weight of the body on the affected side, the patient experiences excruciating pain?

This question is easily answered. The opinion would, I am certain, be unanimous that more or less severe pain on the first attempt to bear the weight of the body on the affected side after a fracture of the shaft of the femur had firmly united, would not be unusual, especially in patients who had sustained or were still suffering from some severe mental shock, and that only the persistence of severe pain, unabated, after repeated attempts at walking would indicate operative interference. That displacement in itself is not a cause of pain nor a barrier to union is frequently demonstrated by patients in whom a shortening of three inches or even more from extensive overriding of the fragments has not prevented union sufficiently strong to bear, without pain or other inconvenience than a limp, the superimposed weight of the body. It must be generally conceded that any fracture of the shaft of the femur in which firm union takes place with permanent shortening not exceeding one inch is a satisfactory result, and that instances in which some shortening is not observed are very rare. A moderate shortening in itself clearly indicates a corresponding overriding or displacement due to the failure to counteract by the usual forms of extension and counterextension the stronger pull of the powerful muscles of the thigh. As a matter of fact, this difficulty has led to the devising of more efficient methods of powerful traction applied directly to the lower fragment itself, as well as to the advocating by Lane and others of the plating of every fracture of the shaft of the femur where the general condition of the patient permits.

The question of negligence based on the failure of the attending physician or surgeon to suggest or advise the taking of an x ray photograph in cases of simple fracture, presents a most interesting as well as a most important topic for discussion. It is peculiarly important in that prior to the case reported in this paper there has been no record in either medical or legal literature in which a plaintiff has been awarded damages on such an allegation.

The question may be discussed most advantageously from the medical as well as from the legal point of view. The medical point of view is best approached by a brief résumé of the history of the x ray. Shortly after its discovery some form of apparatus formed a part of the office equipment of many successful practitioners throughout the country. After a comparatively short time experience taught that the care, the development of its operative technic, and in short the intricate detail necessary to procure satisfactory results precluded its general use, and another specialty was born with the result that many costly x ray machines in the possession of the busy practitioner were quickly consigned to the scrap heap.

Ranking from this time with the specialties, those engaged in it formed a group of which the functions were quite analogous to the functions of special consultants in other branches of medicine. Under such circumstances and with such functions their services in aiding the diagnosis and treatment of cases of fracture were essential only when the
bone at the point of fracture was so deeply seated that accurate diagnosis was impossible or if diagnosis had been made, when the excessive thickening of the overlying soft parts made satisfactory reduction of the fragments difficult. Under these conditions the assistance of the röntgenologist became of great value. Is then the function of the x ray specialist to be extended to those cases of fracture in which the attending surgeon by methods of diagnosis and reduction, evolved through centuries of observation and investigation, can be reasonably certain that the fragments are in such apposition that satisfactory union may be expected? The writer believes that this is no more essential than it is to call a special consultant in every case of pneumonia, appendicitis, or strangulated hernia. Is not, as a matter of fact, the consultant called more frequently at the request of the family than with any hope of benefit from his advice? And is it not with the same spirit, the spirit of self protection, that, in cases of fracture or dislocation, an x ray is suggested when the surgeon is morally certain that the fragments are in apposition or that the dislocation has been successfully reduced? Is not the fear of litigation in the event of nonunion or other unfortunate result, in no way the fault of the surgeon, a very strong incentive for generally advising an x ray irrespective of the location of the fracture? The writer believes that these questions must be answered affirmatively and that it is time to establish the principle that the use of the x ray, although in many instances most desirable, yet in many cases is not indispensable to the proper treatment of a fracture. That such a principle should be established is all the more essential in view of the fact that, having become a specialty, the use of the x ray is frequently inaccessible in many cases of fracture. Should any method of diagnosis or treatment be regarded as indispensable when it is not generally applicable? Should the physician in a scattered community, remote from an x ray laboratory, be subject to litigation because he fails to advise or suggest the need of an x ray? This question is best answered by quoting the legal statute of the State of New York as follows:

"A physician is bound to have a reasonable degree of skill and learning, and having that reasonable degree of skill and learning, he is bound to exercise it with reasonable care, and what his reasonable care is, is that care which the ordinary careful and prudent practitioner usually ordinarily exercises in the locality in which the physician is practising."

In view of this statute the treatment accorded by the physician must be that ordinarily exercised in the community of which he forms a part. In almost no community outside of large cities are efficient x ray machines found, and even in large cities the smaller hospitals are not always provided with adequate x ray apparatus. In the community in which the alleged malpractice occurred no x ray machine was in working order, but this fact did not prevent the judge from connecting this suburb, although twenty miles distant, with New York proper and thereby compelling the defendant to measure up both in knowledge and in efficiency, to a standard which did not obtain in the community in which he lived.

Finally, is the physician or surgeon liable to damages because of his failure to advise a consultant? Irrespective of the nature of the disease or trauma and irrespective of the locality in which it occurred, how endless would be the resulting litigation if such omission constituted neglect. Whether the object of such a suggested consultation were to aid in diagnosis or whether to suggest a way to prolong the life of one hopelessly ill, the frequency of examples of such neglect would be beyond computation. The writer firmly believes that arrangements for consultation are made at the request or suggestion of either the surgeon or some member of the patient's family, and that in the latter event the fact that such a consultation was not deemed necessary and therefore not suggested by the surgeon can in no wise be construed as neglect.

Lack of time precludes the consideration of the many uncertainties connected with the interpretation of the x ray picture itself. It is a well known fact that on exploration a condition may be found essentially different from that which the x ray seemed to indicate and, similarly, deformities may be either exaggerated or minimized by the manner in which the photograph is secured. Space also precludes the consideration more minutely of the question of the inaccessibility of the x ray owing to distance from large centres, and a most important fact, that even in large centres some hospitals are conducted without the advantages of an x ray apparatus, may not have been duly emphasized. Suffice it to say that after careful consideration of the many phases of the question, although in many instances a most important and valuable aid in the diagnosis and treatment of fractures, the use of the x ray must not be judged indispensable, and the neglect to advise its use should in no instance constitute a basis for the recovery of damages. Should such a principle prevail the time is not far distant when the prospect of litigation will prevent those most competent from undertaking the care and treatment of cases of this character.
of the disease. On the other hand, Aufrecht, Kronig, Goldscheider, Ewart, Lees, L. C. Minor, and many others maintain that if we are to detect tuberculosis in its incipiency, we must resort to percussion, and that when auscultation shows positive signs, we are dealing with an advanced stage of phthisis.

Similarly, when we consult the various textbooks on the subject we find an amazing, almost bewildering difference of opinion as to the proper technic to be followed. As Mannheimer well says: "The art of percussion and auscultation, as well as our knowledge of physical signs, has made little progress during the last decade. At present we have arrived at a stage where we do not understand one another when we speak of certain physical signs." Indeed, such a simple question as whether the percussion stroke should be light or heavy is answered differently by different clinicians of first rank. Austin Flint, senior, advised the use of two or three fingers conjoined when great force was necessary. The modern textbook on physical diagnosis by Cabot says that "it is necessary to percuss very strongly when examining the back of a muscular man;" while in the front of the chest a lighter blow suffices. However, Cabot warns against heavy percussion, which he says is always inaccurate. John C. Da Costa, in his recent textbook, says that "the force of the stroke is strong or light according to the situation of the organ or lesion percussed, whether deep or superficial." Most of the books and monographs on physical diagnosis and on tuberculosis, that have appeared in recent years in Europe, insist that only light percussion is to be practised if we are to obtain reliable results. Kronig, Turban, Goldscheider, Lees, and many others advise very light percussion for the detection of early lesions in the apices, and Sahli repeats the maxim that only very light percussion, properly performed, can give the best results. Bonney, Brown, and others in this country, are also in favor of light percussion, and C. L. Minor, in one of the best chapters on the diagnosis of tuberculosis published in this country, says that "too much stress cannot be laid on the importance of light percussion in a large proportion of cases and localities, the occasions when heavy percussion is needed being increasingly rare with increasing skill of percussion." 

Taking another important point of technic,—that of the application of the pleximeter finger to the chest wall—we find again many divergent opinions. Flint, Da Costa, and most of the older writers, maintained that in order to obtain good results the finger must be pressed firmly against the chest wall; Bonney says that if due attention is not paid to this important feature the resonance can be appreciably diminished in intensity and, in many cases, will pass off of "cracked pot" resonance. Cabot also argues that the pleximeter finger must be pressed as firmly as possible upon the surface of the chest; while John C. Da Costa advises that "the more forcible the percussion stroke, the firmer should be the pressure of the pleximeter finger, and vice versa." On the other hand Sahli warns strongly against such pressure and emphasizes that "the pleximeter or finger of the left hand serving this purpose should be brought into very light contact with the surface of the body. The mere weight of the finger is sufficient."

Many other differences of opinion could be quoted from recent works showing the utter lack of unanimity in such an apparently simple matter as the technic of percussion. To illustrate—there are two pictures in Cabot's Treatise on Physical Diagnosis showing the proper and the wrong position of the patient during percussion of the back (pp. 124-125) emphasizing the importance of having the patient bend forward with each arm crossed to the opposite shoulder. In H. Barth's Sémiologie de l'appareil respiratoire, there are also two pictures, showing that when the patient crosses the arms and bends forward the position is defective for percussion of the back, while the position which Cabot shows as wrong, is considered as "la bonne posture du sujet pour la percussion," by this French author. The confusion and bewilderment of the average student when he attempts to study up this point can well be imagined.

The results of these differences in the technic of percussion are in evidence in any hospital, clinic, or physician's office. Percussion is either perfunctorily performed, as an aim in itself, to impress the patient, or is altogether omitted. Many physicians, even such as devote all or most of their practice to pulmonary diseases, rely solely on auscultation for the diagnosis of tuberculosis. There is no doubt in my mind that this is one of the reasons why incipient cases are so rarely recognized.

During recent years several clinicians have attempted to bring about some order in the literature of percussion. A number of excellent investigations of the problems, methods, and technic of the percussion of the heart and lungs have been published in Germany and France, but judging from recent textbooks and monographs on physical diagnosis and on tuberculosis, the results attained by these investigations have not been given the attention they deserve in this country. This is especially to be deplored when the percussion of the apices is considered. It is a well established fact that tuberculosis begins as an infiltration, and can in most cases be recognized clinically in its earliest stages by the detection of dull areas over the pulmonary apices. The reason why so few make use of this method of examination is that many have not yet forgotten the old methods and technic of percussion, which were rather coarse:

---

small areas of airless lung tissue can only be detected by gentle percussion.

It must be stated at the outset that while discussing apical percussion in this paper at some length, no details will be given about the qualities of the percussion sound or resonance. Pitch, duration, and intensity of the sounds will not be considered; nor will special changes in the quality of the sound be elicited—such as amphoric or metallic resonance, the bell sound, cracked pot resonance, etc., as well as the modifications of the sounds obtained by opening or closing the mouth, or by posture, etc.—be discussed. In this paper we are concerned with percussion in cases of incipient tuberculosis. When any of these modifications of the percussion sounds appear, we are not dealing with an incipient case, and we can easily make a diagnosis from the history, symptomatology, and course of the disease. In small infiltrations of the apex, the vibrations set up by percussion produce simple tones, easily recognized by any one who looks carefully and attentively for them. The differences between the resonance in the normal lung and the lack of resonance, or the dulness at the spot over the infiltration can be appreciated by anybody, even one who has no musical ear. If we bear this in mind we have overcome nine tenths of the real and alleged difficulties of the art.

The object of percussion the thorax is to ascertain any pathological changes in its viscera. In percussion the apices, where nearly all the initial lesions of pulmonary tuberculosis in adults are localized, we aim at detecting small foci of infiltration; large airless areas can be ascertained by other methods. Bearing in mind that tuberculosis does not begin as a catarrh of the small bronchi, as some believe, but as an infiltration, it is evident that auscultation cannot give any definite clues as to the pathological condition of the apical parenchyma in the early stages of tuberculosis. The initial infiltration can be detected by percussion not as a definite anatomical change, but merely as a substitution of solid, nonresonating material for the normal, porous, air-containing and resonant lung tissue; the alveoli are filled with exudate, or the interstitial tissues contract and compress the alveoli, finally obliterating them altogether. Inasmuch as altered breath sounds and râles can only be found in the pulmonary apices when lesions of secretions interfere with the current of air entering or leaving the air vesicles, it is evident that the first signs of tuberculosis in the apices are not sought by the aid of auscultation. Moreover, the pathological anatomy of the early lesions of pulmonary tuberculosis shows that the first focus is usually located in the peribronchial tissues and the adjacent alveoli, and is usually accompanied by enlargement of the regional lymphatics. All, or some, of these tissues may be involved in the infiltration, producing slaty induration and wasting of the pulmonary parenchyma which is replaced by dark fibrous tissue. Caseous pneumonia, filling the alveoli with a cheesy exudate, may be the initial lesion. As long as the infiltration remains beneath the mucous membrane of the bronchi, the entrance of air into the affected areas may not be interfered with very much, while in the rest of the lung it is circulating freely. But interference with the free circulation of air within a limited area cannot be readily ascertained by auscultation, because the surrounding lung vesicles act in a compensatory manner and suck in more air. Only when the initial lesion is extensive may we find weak vesicular, or at most bronchovesicular breathing in a circumscribed spot. Indeed, I have quite often observed this to be a fact in incipient cases, and have learned to look upon weak or absent breathing localized at an apex as an important sign of incipient phthisis.

Only when the caseous material of the infiltrate softens and breaks through the wall of a bronchus, thus permitting the entrance of air into the disease focus proper, can râles be heard on auscultation; it is also at that time that tubercle bacilli make their appearance in the sputum. When this is the case we can easily make a diagnosis by auscultation, as well as with the microscope, but not before. It is evident that waiting for auscultatory signs to verify a diagnosis of incipient tuberculosis is just as grave an error, as waiting for bacilli to make their appearance in the sputum. When we have râles on auscultation we may be sure that we are dealing with a more or less advanced stage of the disease—caseation and softening of the infiltrated area has already taken place. When the disease process is not located originally in the bronchi, but more in the peribronchial tissues, it is again evident that the air circulating in the bronchial tree cannot reach the focus at all, and the auscultatory findings will necessarily be negative.

Because of faulty technic in percussing the chest, which is quite common, many wait for auscultatory signs in tuberculosis suspects. Very few have learned the elementary lesson that strong percussion over the region of the apex is useless in incipient
cases. Even in other regions of the chest, including the back, light percussion gives better results than the heavy blows which we often see inflicted upon the pleximeter or finger, as well as on the patient. Oestreich and de la Camp, basing their assertions on experiments and autopsies, have shown that only infiltrations located superficially can be demonstrated by percussion; in deep lesions even heavy percussion is of no avail. The percussion stroke, according to these authors, penetrates only to a depth of six centimetres, and from this is to be deducted some two or three centimetres constituting the parietes, so that the percussion blow reaches only three to four centimetres deep into the visceral organs. It is for this reason that we cannot percuss the heart from behind, and it is impossible to locate a lesion situated posteriorly while percussing anteriorly; even at the apex, which is not bulkiest, we may find dulness posteriorly or anteriorly, while on the opposite side the resonance may be normal or even above normal, no matter how strong we percuss. It is also for this reason that we must percuss over all sides of the chest, and even then we do not penetrate to centrally located lesions or enlarged bronchial glands.

On the other hand Goldscheider thinks that the percussion blow does penetrate deeper than indicated by Oestreich and de la Camp. His experiments lead him to believe that the lightest percussion stroke penetrates deeply into the lung tissue and produces acoustic phenomena which are audible to the ear. With very light percussion (schwellenwert Perkussion) on the apex of a lung removed from a cadaver he could hear the resonance distinctly at the base of that lung—a distance of sixteen to twenty-one centimetres according to the degree of inflation. In the lung of a horse he could even perceive light percussion resonance at a distance of thirty-five centimetres between the points of percussion and auscultation. Moritz and Röhl arrived at similar conclusions through ingenious experiments.

These experiments on the lung removed from the body do not prove, however, that similar conditions obtain in the lung of the living man. Because of the elasticity of the thorax a great part of the percussion stroke is dissipated along the muscular and bony parietes, while in the lung alone the percussion wave penetrates sagittally in the direction of the stroke; the medium through which the wave passes is more uniform in consistency when passing through lung tissue alone, than when passing through skin, subcutaneous tissue, muscles, and bones before reaching the lung. Practical experience confirms that the percussion blow, as practised on patients, does not reach deeper into the lung than is claimed by Oestreich and de la Camp—three to four centimetres of the visceral organs. The stronger the blow, the more of the force is conducted laterally by the ribs and the intercostal muscles which are set into strong vibration, and the resonance elicited gives no clue as to any consolidations of lung tissue that may be deeply located. This is especially true of deep infiltrations surrounded by normal lung tissue. It is consequently a vain effort to attempt to reach a deep lesion in the thorax by vigorous percussion. We know from experience that in very obese or emaciated persons it is quite difficult, often impossible, to define the boundary between the lung and the liver. To be sure, strong percussion may give a clear note of pulmonary resonance, but the line thus marked out is usually indefinite, and with very few exceptions, unreliable. Indeed, radiography and autopsies have shown that those who attempt to achieve such results very often err.

In percussion theoretical considerations should be subordinated to bedside experience. If experiments give results differing from those obtained by experience in our daily practice we must conclude that either the experiments are faulty, or their interpretation is erroneous. Experience teaches that deep seated consolidations cannot be definitely determined by percussion, not only because the stroke does not penetrate beyond a certain depth, but for the reason that the vibrations set up in the surrounding aircontaining tissue predominate and lead to confusion.

Once we are clear that only superficial dulness can be reliably determined by this method of investigation we will use only light or gentle percussion, especially when examining the pulmonary apex. This is particularly essential when we attempt to determine the boundaries of the apices, which is most useful in attempts at detecting early lesions of phthisis. "To appreciate superficial boundaries," says Sahli, "is a good general rule that we should percuss as lightly as possible, and a good criterion of the desired strength is to evoke practically no note over the dulled areas." In most cases I have found it advisable that the movement of the percussing finger should be almost entirely from the metacarpalphalangeal joint. The percussion note elicited is a faint sound which can only be appreciated while listening attentively. Of course perfect silence must be maintained in the room. While by this method the resonance can not be demonstrated by bystanders, yet the physician who practises it is often able to detect areas of dulness which cannot be found by any other means. When reaching an airless area the contrast between the resonance evoked in the air containing area, and the deadness met with at the dull spot is striking. As Goldscheider well says, it is easier to appreciate a difference between something and nothing, than between one
thing and another which differs but slightly from it. Over resonant areas we evoke a note, while over dull areas, no note is brought out at all.

It must be borne in mind that while solid, airless lung tissue will usually give a short or dull note on percussion, there are many exceptions. Oestreich points out in many apical lesions there is a proliferation of tissue, so that the volume of the apex is increased, making the air containing lung tissue around the focus less expansive than normal. As a result we may get in this class of cases a tympanic note. Another source of error is varius emphysis, a part of the apex which may appear near a shrunken area and thus mask the dulness of the airless part. But this is extremely rare in incipient phthisis, which is always accompanied by shrinkage of the apical parenchyma, as will be shown later on. Small areas can only be detected by very light percussion, so light that the sound becomes altogether inaudible when we reach areas of defective resonance, or flatness. In many cases of incipient phthisis we find at the apex small areas of dulness elicited by light percussion, but when the stroke is somewhat heavier the dulness disappears and resonance, or even tympany, is elicited. This is usually the case with small, disseminated infiltrations scattered through the apex. This fact can be utilized for the determination of the extent of the lesion. Bearing in mind that the lightest stroke penetrates quite deeply enough for our purposes, that a stronger blow does not reach deeper into the pulmonary tissue, but sets up stronger vibrations, especially in a lateral direction, we may conclude that the absorption of the sound by the airless areas of the lung is, for this reason, less perfect with strong than with light percussion. The more consolidated the parts are, the less muffled will the sound appear in spite of the increase in the force of the percussion blow. It is for this reason that small areas of dulness can only be detected by light percussion, and they disappear when the blow is increased. If on increasing the force of the blow the dulness remains, we may be sure that we are dealing with extensive areas of airless tissue.

It is remarkable that, unconsciously, clinicians have always followed these principles in their efforts to use the proper force while percussing. Instinctively we percuss three or four times over the same spot. If these strokes are carefully observed it will be noted that not all are of the same force. They make a crescendo or decrescendo—unconsciously an attempt is made to find the proper force for the given spot. Experienced men find it quickly; the master may find it with the first stroke, but even he is compelled to percuss several times when he wants to delineate dulness in abnormal areas.

When the quantity of air in the lung is diminished we shall obtain tympany, due to a relaxation of the pulmonary tissue; but when the tension is increased the tympanic note disappears. Many small disseminated solid nodes of airless tissue within a normal lung apex are capable of producing a dull tympanic or "boxy" note on percussion. At times tympany is the first sign to suggest such a lesion in incipient apical involvement. The note elicited is somewhat clearer, of a tympanic character amidst normal resonance, while dulness is not yet evident. The latter is predominant when contraction of the apex exerts a perceptible influence.

Next to light percussion, it is important to bear in mind that firm application of the pleximeter finger is apt to give misleading results. It seems to me that light percussion is not gaining in vogue, considering the rarity to which we see it practised, because those who have given it a trial have retained the old traditional method of pressing the pleximeter finger with great force to the surface of the chest. "The whole secret in percussing superficial boundaries," says Sahli, "depends on two principles—light percussion and light contact." Strong pressure of the pleximeter finger dissipates all the advantages of light percussion, as can be readily ascertained by first applying the finger lightly and percussing gently till a dull area is encountered; now the pleximeter finger is pressed firmly to the chest wall and again a light stroke given—a resonant note is usually the result. The reason is that the pressure of the pleximeter finger brings the intercostal muscles into strong tension, making of them a large pleximeter which brings out the resonance of the neighboring air containing lung. The dulness obtained under such conditions can not be delineated.

Another old, but very bad method of percussion is to apply three or four fingers of the left hand to the surface of the chest and to percuss each one successively, "a change from dulness to resonance is often thus brought out with unusual clearness," says the author of a very popular textbook on diagnosis. Any one who thus attempts to localize a lesion in the lung will be sadly disappointed, unless the consolidation is very extensive; a few taps with the fingers directly on the chest, without the aid of a pleximeter or finger, will give much better and reliable information.

Bearing in mind that, as a rule, tuberculous lesions spread from above downward and that the line between healthy and infiltrated pulmonary tissue usually runs horizontally, we percuss from above downward, or the reverse in horizontal zones. The pleximeter finger must be placed parallel with the ribs and not perpendicular to them as is often practised. It is obvious that when the pleximeter finger is placed vertically on the chest we obtain mixed resonance because the stroke brings into vibration both, healthy and diseased lung tissue. It is also important that only intercostal spaces should be percussed because percussion of the ribs which in themselves can be considered long pleximeters,
FISHBERG: PERCUSSION OF THE PULMONARY APICES.

The clavicle brings out a resonance due to vibrations of large areas of lung tissue lying laterally and not only under the spot which we intend to strike at the given moment.

In the diagnosis of apical lesions, when we try to find small areas of airless tissue, it is often difficult to localize dulness when the entire pleximeter finger is applied to the chest wall. Plesch, in Germany, and Mannheimer, in this country, have suggested that the pleximeter finger be flexed at the second phalanx to a right angle, the pulp only is then applied to the chest and the distal end of the first phalanx is percussed. This maneuver often enables us to delimit the boundaries of the apex with greater exactness than the usual application of the finger to the chest wall, and in mapping out Krönig's resonant field, it is often invaluable.

The diversity of opinion as to the position of the patient while the chest is being percussed has already been mentioned. Auenbrugger, the inventor of percussion, insisted that the thoracic muscles must be tensely contracted, because he used no pleximeter, and with relaxed muscles clear resonance cannot be brought out. This can be easily verified by percussing one's own pectoralis major muscle—only when the muscle is rigidly contracted can a clear resonant note be elicited. As we percuss at present with a finger or pleximeter, Auenbrugger's methods is in most cases not the best, especially when light percussion is practised; the tense muscle is a great hindrance to exact localization of any dulness that may be found. Indeed, great efforts are being made at present to have as small a pleximeter as possible with a view of having the stroke penetrate more in the direction in which it is sent, and to avoid lateral conduction, while a large muscle serving as a pleximeter will do the exact opposite.

Relaxation of the patient's muscles is best at-}

by the various authors, and they served the purpose of discrediting apical percussion in early tuberculo-
sis until within recent years, when Krönig and Gold-
scheider reinvestigated the problem. We now know
the importance of a careful and methodical percus-
sion of the apices as a great aid in the diagnosis of
incipient tuberculous lesions. That the teachings
of these two clinicians have not been given due
credit in this country is evident, from the fact that
of all the text books on diagnosis I have at hand,
only two mention Krönig's method, and those only
cursoryly; Mannheimer alone describes it in detail
in an excellent paper on the Exploration of the
Chest; L. C. Minor gives details about apical per-
cussion according to Krönig and Goldscheider in
Klebs' Treatise on Tuberculosis.

The most important lesson taught by these two
clinicians is that percussion in general, and of
the apices in particular, must be done very lightly—
the stroke given over the pleximeter or finger must
be gentle and soft, hardly audible and hardly distinc-

The technic of percussion is the detection of areas
in which the normal content of air is diminished or
absent. In case the apex is extensively infiltrated
with tuberculosis or other lesions, it will contain
less air than normally, and the resonance elicited
by percussion will be defective when compared with
the normal side. Any percussion, immediate or
mediate, light or strong, will do in cases with ex-
tensive lesions. But these cases can be readily di-
agnosticated by the symptomatology alone. On
the other hand, in case the air content of the apex
is only slightly diminished, as is seen in incipient
phthisis, strong percussion sets into vibration a
larger area of lung tissue, including adjacent
healthy parts of the apex, and the resonance does
not differ from that found in the opposite healthy
apex. Indeed, it is well known that comparative
percussion of the apices is only of use when the
focus is located superficially, or subpleurally; when
the lesion is centrally located, neither strong nor
light percussion may give any satisfactory infor-
mation because the superficial, healthy lung tissue acts
as a resonator, and for other reasons already men-
tioned.

The fact that in the vast majority of cases of
tuberculosis shrinkage occurs quite early is of great
assistance in diagnosis. Topographical percussion,
according to Krönig's method gives an outline of
the apical resonant areas which, with certain
reservations, is pathognomonic of incipient phthisis.
It projects anteriorly and posteriorly a picture of
the height and width of the resonant areas in these
regions. If the resonant area on one side is smaller,
shorter, or narrower, we may safely conclude that
the apex is shrunken.

A study of the resonant areas in the supraclavi-
ular and supraspinous fossae in the normal indi-
vidual has shown Krönig that they project as cones
anteri orly and posteriorly, and that these two cones
are united on the top of the shoulders by a narrow
strip of resonance—the isthmus (Figs. 2 and 3).
With careful and very light percussion we can eas-
ily map out the mesial line which runs in front, be-
ginning at the sternoclavicular articulation, upward
and outward forming a concavity inward; while
posteriorly the line forms a convexity and ends at
the level of the lower border of the second thoracic
spinosus process. The external line separating the
resonant apex from the dull shoulder and neck
runs from the middle of the anterior border of the
trapezius, curving downward and reaching the
clavicle at the junction of the middle and outer
third, and continues obliquely toward the axilla;
proceeding upward it forms a convexity toward the
neck, crossing the shoulder, on the top of which it
is separated from the mesial line by a resonant space
of about two to three centimetres forming the isth-
mus, and proceeding downward with its concavity
outward, terminating a couple of centimetres out-
side of the middle line of the scapula. Normally
the height of the apex is anteriorly about three to
four centimetres above the clavicle, and posteriorly,
on a level with the first thoracic spine, about two
centimetres outside the middle line of the body.

When the resonant areas of the apices are mapped
out on the chest it is expected that both sides should
be of nearly the same height and width. In cases
of phthisis it will be found at an early stage that
the affected apex is narrower and shorter than the
other, due to shrinkage which appears quite early,
as has already been indicated (Fig. 4). When
nothing else connected with the clinical history of
the case could verify the diagnosis, I have often
been able to acquire a strong suspicion, or make a
positive diagnosis by the aid of Krönig's method
before auscultatory signs have given any indication
of an apical lesion.

The technic of the percussion of Krönig's re-
sonant areas is very simple and can be easily ac-
quired by any one who takes pains in careful prac-
tice. Indeed, it is much easier to learn than com-
parative percussion, and requires no musical ear.
Of course a light and soft percussion stroke is im-
perative, and a strong or even medium blow will be
of no use in many cases. The patient should
sit on a round high stool, with his arms hanging
down at his sides in a relaxed condition, or resting
on his knees. I have often found it better to have
the patient lying on an upholstered couch, or an
examining table—the resonance is then brought out
to a better advantage. Placing the patient with his
back near a door or wall, or, as Lawrason Brown
has suggested, standing the patient in the angle be-
tween two walls, may be of immense service in
bringing out points which may otherwise escape at-
tention. Krönig states that it is easier to map out
boundary lines by percussing from the dull area to-
ward the resonant. Most authors agree with him.
I have, however, found the reverse to be of greater
service. It is important to remember that the plexi-
meter finger must be applied parallel with the line
we expect to delineate—in this case at right angles
with the clavicle.

Krönig's method of percussion is of excellent
service in a large proportion of cases of incipient
phthisis. But we often meet with patients in whom,
after careful and time consuming work, the result
attained is unsatisfactory. I have seen cases in
which no dislocation of any of the lines of demarca-
tion of the apical resonant areas could be deter-
mmed, but other symptoms and signs of tuberculosis
were found and were confirmed by the subsequent
course of the disease. Nor can I entirely agree with
Krönig, when he says that in phthisis the motion of the base is invariably affected at an early stage, while in nontuberculous apical lesions the expansion of the lower margins of the lungs remain normal. Admitting the fact that adhesions of the pleura are found at the base, due to former attacks of pleurisy—it may be found occasionally with collapse induration of the right apex—there are many incipient and moderately advanced cases of tuberculosis, in which the base retains its normal mobility during expiration and inspiration.

The reason for the occasional failure of this method of percussion is to be sought for in the fact that Krönig's resonant areas are not an outline of the true anatomical apex, but merely a projection of the same lung tissue in various directions (Figs. 5 and 6). The fact is that it is impossible to project the top of the lung on the surface of the body, considering its peculiar anatomical position and form. Krönig's isthmus, for instance, does not exist at all, and we must remember that only the mesial border corresponds to the anatomical margin of the lung anteriorly and posteriorly. The lateral border cannot be determined with exactness because the percussion waves strike the spot tangentially. Several attempts have been made to invent a method of percussion, which would show the resonant areas of the true pulmonary apices. The best of these methods is that of Goldscheider, though it is to be deplored that so few practitioners in this country have adopted it.

Goldscheider's method of percussion can be intelligently applied only when the normal topography of the apices is borne in mind. Physical exploration and fluoroscopic investigations have shown that in healthy persons the height of the two apices is the same on both sides, and that asymmetry in this respect spells disease of the lung or pleura. Anteriorly, the apices are located in the supravclavicular fosse, between the heads of the sternocleidomastoid muscle, where they are not covered with thick muscles, thus allowing excellent opportunities for percussion. It must be emphasized here that percussion outside of the external border of that muscle gives lung resonance only tangentially, not directly. The highest point of the apex is on a level with the lower end of the thyroid, about three to four centimetres above the clavicle. Behind, the apex lies close to the spinal column, reaching above the level of the spinous process of the vertebra prominens, about two to three finger breadth from the median line of the body. At the second thoracic spine the two apices converge, running along the spinal column, as can be seen from the diagram. (Figs. 7 and 8.)

The supravclavicular fossa cannot be percussed as a unit. Taking its anatomical peculiarities into consideration, Goldscheider divides this region into three divisions, each of which has a different significance from the standpoint of percussion. Through this fossa passes the first rib, which together with the sternum and the first cervical vertebra forms the aperture of the thorax through which the real apex of the lung passes. There is also to be found in this region a part of the first intercostal space. The first rib surrounds the apex of the lung, indenting it with a furrow. The first pair of ribs form an incline, sloping downward anteriorly with an abruptness varying in different individuals, the highest point being on a level with the two upper thoracic vertebrae, so that anteriorly the apices project 1.5 centimetres above the first rib, while behind the latter is higher than the apex by one to two centimetres. Bearing all this in mind we must, while percussing the supravclavicular fossa, distinguish three parts: the apical part—the part of the lung passing out of the aperture of the first rib: the first rib with the part of the lung which it covers; and, finally, the narrow strip which is part of the first intercostal space. (Fig. 9.) It is because of the peculiar anatomy of this supravclavicular space, that the apex cannot be percussed as a unit—vibrations are produced not only in the apical pulmonary tissue, but also in the subapical region, the first rib being short but very wide, when struck with a percussion blow, it emits its own sound and sets into vibration other parts of the lung, and the resonance thus elicited is a mixed and rather confusing one. Moreover, the area between the trapezius and the sternocleidomastoid, over which most physicians are apt to percuss, does not contain the pulmonary apex at all, as is clearly shown by the accompanying illustrations. (Figs. 5 and 8.)

The height of the apex anteriorly, as well as its mesial border, is best delimited by percussing between the heads of the sternocleidomastoid downward to the clavicle and beneath it, while the patient's head is turned to the opposite side without bringing the muscles into great tension. Under normal conditions the resonance elicited is equal on the two sides, or nearly so, and for practical purposes the slight difference between the resonance of the right and left sides may be disregarded. On the other hand, differences in the height of the apices, or in the outlines of their mesial borders when the two sides are compared, are of profound significance in showing pathological changes in that part of the lung. The external border of the apex is not looked for at all for the anatomical reasons stated above.

Goldscheider has also shown that it is a vain effort to percuss the supravclavicular fossa, and practical experience has shown that he is right. With the scapule in their normal position we find that the greater part of each supravclavicular fossa is beyond the bony thorax, and the apex of the lung is only partly covered by the scapula. (See Fig. 8.) To hammer away in the supravclavicular fossa, as we see often done, is a waste of time and energy. Percussion of the scapular region strikes bone and thick muscles and hardly, if at all, does it penetrate to the lung. But with folded arms over the opposite shoulders, or the patient embracing the back of a chair, he moves the scapula outward as far as possible, thus exposing the lung, covered by comparatively thin pareties. (Fig. 10.) Bearing in mind the topographical anatomy of the posterior aspect of the apex, we attempt to determine the upper limit of the lung and the course of its mesial.
border, which is even easier to outline than anteriorly. The external margin is difficult to make out clearly, and is of little importance in diagnosis.

With very light percussion we sometimes find small areas of dulness in these regions which could not be found otherwise. It is best to use, especially anteriorly, the hooked finger as a pleximeter. By asking the patient to lift his arms over his head we can percuss high up in the axillary region where we may detect any dulness in the first intercostal space. Cases are not at all rare in which this is the first place in which dulness reveals an infiltration of the apex which could not be found anywhere else. Special attention is to be given to the upper and middle parts of the interscapular spaces, where enlargements of the bronchial glands may be determined by finding dulness.

We percuss the apex both unilaterally and bilaterally. Unilaterally we determine the height of the apex and its mesial border, and bilaterally we study the comparative resonance. The pleximeter finger must be applied lightly, using the same pressure on the chest wall each time we apply it; each stroke must be applied with the same force, in the same direction, and during the same period of respiration. It is best to begin with the lightest percussion, preferably anteriorly in the third intercostal space, posteriorly opposite the spinous process of the fourth or fifth dorsal vertebra and proceed upward. If defective resonance is discovered, the force of the stroke should be diminished to a minimum, and when the area of dulness is delimited the force of the stroke is increased gradually, always having in mind the thickness of the integuments, with a view of ascertaining the degree of the dulness, as well as any shrinkage which may have taken place. Small areas of infiltration can only be detected by very light percussion; so light, that the defective resonance disappears with the slightest increase in the force of the stroke. If on increasing the percussion force the dulness remains, we may be sure that we are dealing with extensive areas of airless lung tissue.

Bearing in mind that the apices have physiologically a weaker resonance, we percuss gently while proceeding from the above mentioned areas upward with a view of ascertaining the upper limits of the apex. In incipient phthisis we may find that one of the apices is lower than the other, and also that the note elicited is shorter, or muffled, while its mesial border is moved outward.

A study of the changes in the percussion note during extreme and held inspiration and expiration is of great assistance in doubtful cases. J. M. Da Costa, about forty years ago, was the first to draw attention to this mode of percussion, and while in Europe most of those engaged in the study of the physical signs of tuberculosis have emphasized the importance of “respiratory percussion,” as Da Costa called it, it has almost been forgotten in this country. Da Costa showed that “at the apices, and especially in the infracavicular region, in the supraspinous fossa, and on a line toward the spine, a full held inspiration increases the resonance, makes the sound fuller, and raises the pitch; and where, as is so common, the left side has normally a higher pitch, this disparity is preserved.” A held and complete expiration will greatly lessen the resonance and lower the pitch at the apices. “In the held inspiration we obtain a greater mass of tone; in held expiration, the reverse.” This change of resonance was found by Da Costa to remain unaffected in bronchitis, but in phthisis, even in its earliest stages, the affected area shows the reverse—a long, held inspiration gives a duller note than that observed on the healthy side.17 Da Costa, apparently, did not practise light percussion as is in vogue at present. It is, however, a fact that this change in the note, observed during long held inspiration and expiration, is brought out more strikingly and clearly by light percussion than with strokes of moderate force, and this method is of immense value in many cases which are not otherwise clear. When the infiltration increases in extent, involving the larger part of the apical parenchyma, the dulness on percussion is no longer modified by the forced and held inspiration and expiration. Hence we have in this method a very good test as to the extent of involvement by the tuberculous process.

There remains yet to be discussed the clinical significance of small circumscribed areas of dulness in the apices. Are we justified in considering every case showing a contraction of Krönig’s resonant field on one side, having one apex shorter than the other, thus indicating retraction of the pulmonary tissue, or showing a dislocation of the mesial border of an apex, etc., as a case of active phthisis? This is by no means the case. In this respect, percussion is just as liable to lead to erroneous conclusions as is radiography, or even post mortem examination of the lung and pleura. The radiographer is not justified in asserting, without qualification, that he deals with an undoubted case of tuberculosis because he finds a shadow or mottling on the plate at one or both apices or roots of the lungs. H. Sewall and S. B. Childs, after a careful radiographical study of the chest, conclude, that while extreme pathological changes in the lung and glands may be recognized with great facility, alterations of a moderate grade need careful judgment in their interpretation; and that, in the x-ray negative of the normal chest, the opaque arborizations of the “bronchial tree” are almost wholly composed of shadows cast by blood vessels,18 which may and may not be caused by tuberculous infiltration. It is noteworthy that even the pathologist, making an autopsy, is not justified in diagnostinating tuberculosis because he finds some induration of the regional lymph glands at the hilus, diffuse calcification, or scar formation in any part of the lung or pleura. Formerly pathologists did make unqualified diagnoses upon finding small scars or calcified areas in the glands or lungs, but recent investigations have shown that this is liable to be erroneous. According to Goerdeler, who recently published a thorough study of the pathological anatomy of tuberculosis, only infiltrations of the lungs or of bronchial gland tissue showing tuber-

culous tissue proliferation, or tuberculous cheesy material, can be considered as positively of tuberculous origin, while all other findings may be due to causes other than acid fast bacilli. As just as the radiographer and the pathologist must be careful in their interpretation of the findings in such cases, especially in changes of moderate degree, so must the clinician be careful in his interpretation of small areas of dulness elicited at the apices of the lungs.

Practical experience teaches that in the normal man, the resonance elicited by percussion is practically the same on both sides of the chest from the top of the apex to the base; that there are no shadows or mottling to be seen on the fluoroscopic screen or on the radiographical plate, in any part of a chest containing normal lungs; and that there are no scars, inductions, or calcifications in the normal lung and pleura. But there are many exceptions. Scoliosis, even of a slight degree, influences the percussion resonance, and also the x-ray picture. In fact, in the major forms of spinal curvature percussion is of little value, as is radiography, for the purpose of discovering small circumscribed lesions of the lungs. The musculature of the right side of the chest is more strongly developed than that of the left, especially in hard working people, and this has an important influence on the percussion resonance. The same is true of asymmetry of the upper aperture of the thorax, which is quite common. There are persons in whom the resonance on both sides is duller than normal, without any excessive adiposity or strongly developed muscles to account for this defective resonance. It must also be borne in mind, while percussing the chest, that the air content of the lung is less in childhood than in later life, and that it decreases during old age, often without showing any anatomical changes in the lung tissue on the autopsy table.

These and many other factors which have an influence on the percussion resonance are to be taken into consideration before drawing conclusions as to the presence or absence of an active tuberculous lesion from percussion findings. Moreover, physical diagnosis in general, and percussion in particular, does not reveal diseases, but only anatomical changes. Dulness in an apex shows that in that region there is an area of lung tissue which is devoid of air; the physician must determine the cause of this airless area by a careful and painstaking analysis of the auscultatory signs if there are any, and especially from the history, symptomatology, and course of the case. If in addition to the circumscribed dulness, or contraction of Kölög's resonant area, or shortening of the apex on one side, etc., we have a history of exposure to tuberculosis, a cough for a period of several weeks, a loss of weight, and last but not least, tachycardia and an elevation of temperature every afternoon or evening, we may safely conclude that we are dealing with a case of incipient tuberculosis, even if auscultation gives no definite signs. On the other hand, dulness of an apex, even of an extreme degree, without any of the general symptoms just mentioned, may be due to many causes other than tuberculosis. A common cause of retraction of the right apex is nasal obstruction, effective in producing collapse induration which is often mistaken for tuberculosis and treated as such. This may be, as a rule, easily excluded if the history and course of the trouble is carefully considered. Healed tuberculous lesions of the apices are another source of error when we reply solely on percussion, just as in radiography. I have also observed and described some cases of heart lesion, especially mitral stenosis, in which dulness was to be found at one apex, mostly the right, while the other side may be overresonant, or even tympanic. Inasmuch as cough, hemoptysis, dyspnea, loss of weight, debility, etc., are not uncommon in these cases, they are often diagnosed as tuberculosis. It is a curious fact that many who rely more on auscultation than on percussion, in the diagnosis of early tuberculosis, fall into errors of this kind, and give as the reason for their mistakes, the percussion findings, forgetting that in many cases of heart disease impairment of resonance is found at one or both apices.

With the judicious reservation of the conditions just mentioned, percussion is of greater value in the diagnosis of incipient tuberculosis than is auscultation.

RECAPITULATION AND CONCLUSIONS.

Pulmonary tuberculosis begins as an infiltration and not as a catarrh. It can therefore be recognized in its early stages by the detection of small airless areas of lung tissue at the apices. When auscultatory signs make their appearance, it is an indication that the infiltrate has softened, and broken through a bronchus, and the case can no more be considered incipient.

The percussion stroke penetrates only about six centimetres into the chest, and a light stroke is sufficient to bring out superficial dulness. Centrally located airless areas, such as bronchial glands, etc., surrounded by normal lung tissue, can not be demonstrated even by very strong percussion. The stronger the blow, the more its force is dissipated along the elastic ribs and intercostal spaces which vibrate strongly, and give no clue as to the condition of the spot lying vertically beneath the stroke.

Light percussion is sufficient in most cases, especially at the apices. The contrast between the resonance of the air containing tissue and the deadness of the airless spot is striking when light percussion is practised. The sound becomes entirely inaudible when areas of defective resonance are reached.

Small disseminated foci of airless tissue can only be found with light percussion; an increase in the force of the stroke in such cases may evoke a normal, or overresonant note. If on increasing the force of the stroke the dulness remains, we may safely conclude that we deal with an extensive area of airless tissue.

The contact of the pleximeter finger with the chest wall must not be too firm, thus avoiding tension of the intercostal muscles and their conversion into large pleximeters. Care must also be taken to percuss only intercostal spaces, because
placing the pleximeter finger over a rib prevents localization.

In most cases of tuberculosis shrinkage of the apex occurs quite early, and the determination of a narrowing of the resonant area in the supraclavicular and supraspinous fossae on one side is of immense value in the diagnosis of early tuberculosis. By mapping out the resonant areas on both sides anteriorly and posteriorly, any disparity appears quite vividly at a glance when the two sides are compared.

For practical purposes it is sufficient to percuss the apex in its true anatomical position, which is anteriorly between the heads of the sternocleidomastoid, reaching about three or four centimetres above the clavicle; and posteriorly, close to the spinal column to the height of the vertebra prominens. A shorter apex on one side is of immense significance. The resonance also must be of about the same intensity on both sides; the outline of the mesial borders of the apices can be easily ascertained by careful percussion, and it is expected that both sides should have the same course.

Percussion of the supraspinous fossae proper, over the scapula, and anteriorly between the trapezius and the sternocleidomastoid is a vain effort —no pulmonary tissue is located there.

During extreme and held inspiration, in the normal lung, the resonance is increased, while during forced expiration the resonance is duller. In infiltrated apices a long and held inspiration gives a duller note on percussion than is found over the opposite, healthy side, and this is often of great value in doubtful cases.

In the interpretation of percussion findings in the apices, the sources of error are of about the same character as those met with in radiography. The fact that physical diagnosis only shows anatomical changes, but does not identify diseases, must always be borne in mind. Small areas of dulness over an apex indicate airless areas of lung tissue at the spots where they are found. Whether these airless lesions were caused by a tuberculous infiltration, and whether the tuberculous process is active at the time of the examination, can only be determined by a careful and painstaking study of the history, symptomatology, and course of the disease. If the latter point to a tuberculous infection, we may safely make a diagnosis of tuberculosis without any definite auscultatory signs.

ORAL SEPSIS AND ITS POSSIBLE DANGERS.*

By Randle C. Rosenberger, M. D.,
Philadelphia,
Professor of Hygiene and Bacteriology, Jefferson Medical College; Professor of Hygiene and Preventive Medicine, Woman's Medical College, Philadelphia.

The mere presence of various types of bacteria in the mouth does not mean oral sepsis: nor does the presence of a few pathogenic streptococci, pneumococci, even diptheria bacilli mean that a disease exists. It is well known that certain individuals harbor virulent forms of organisms and yet do not suffer from infection in any form at all. When this person comes in contact with another, less susceptible, the latter contracts disease in some form or other.

This is a problem that has existed for years, and it is only by assuming that the carrier possesses greater resistance than the other person that we can presumably explain the phenomenon. In the mouth of every individual, no matter how careful he may be in personal hygiene, there exists many forms of bacterial life. Most of these forms are nondisease producing and hence are made up mostly of saprophytic bacteria. These forms live on the desquamated epithelia, upon food particles, and where decay exists flourish in cavities, no matter how small or insignificant the cavity may be. Where the enamel has been destroyed or removed, where erosions of the teeth exist, here bacteria start to make inroads upon the dentine, and in a short time the dentinal tubules are infected, the infection spreading very rapidly, the organisms being made up for the most part of the types normally existing in the mouth.

Where stumps of broken or decayed teeth are present the infection is, it seems, possibly worse, on account of the proximity of the gums and infection of these parts is nothing uncommon. The presence of stumps of teeth which appear to be just on a line with the gums is too often observed to need any added description, but the reddened, swollen, puffy gums are parts which should also be protected and treated. There is no doubt in my mind that the condition of the gums is secondary to that of the necrosed teeth and that if removal of the stumps or careful cleansing of the teeth and mouth had been practised, no such condition would have resulted. Erosions, long continued ulcers, and small abscesses form where such areas exist. Where a stump or a broken tooth exists, where decay has once begun in that tooth the process is absolutely and progressively constant until the whole tooth is destroyed. Now, if such a decayed tooth or stump is improperly capped with the ready made crowns the bacterial invasion does not cease, the products of decay are formed, and in this chamber (it might be called), under partial anaerobiosis, decay is progressive. How often do we see the black, or yellow discoloration of teeth above the cap? How often do these caps become loose and allow the accumulated products of putrefaction and decomposition to be squeezed out by manipulation of this cap? The cheap, advertising dentists who fill a person's mouth with these appliances are doing incalculable harm, for he does not care about the condition of the teeth for capping; all he cares for is his fee, which he most always gets. If the cap or crown is carefully and properly adjusted, surrounding the tooth at the proper level, and fitting the gum properly, very little if any trouble should arise. No cap should be applied until all decay has been removed and the tooth properly filled.

An infection which is now receiving more attention than formerly is Vincent's angina. This process is due to the symbiotic organisms, the spirillum

*Read before the State Medical Society of Pennsylvania, Section of Medicine, September 25, 1913.
and the fusiform bacillus of Vincent. It is characterized by ulcerative, membranous, or ulceromembranous process, and where extensive may be mistaken for diphtheria. It may be located upon the margin of the gums, upon the cheeks, lips, tonsils, or larynx; and may be very benign or may be a fatal form of infection. In several cases marked edema of the throat and larynx have occurred and death supervened, but in the majority of cases it lasts only a few days.

Either organism—the spirillum or the bacillus of Vincent—may be found in the secretions of the normal mouth, yet when both occur it constitutes Vincent's angina and an ulcer or membranous condition is usually found in the locations mentioned.

One of the most troublesome, long standing, and resistant infections of the mouth is pyorrhea alveolaris. The bacteria found in this infection are principally those of suppurition, but it must not be lost sight of that some systemic disease or diathesis is probably at fault. A process which has as its ultimate effect the loosening of the teeth with loss of these structures seems to have some other cause than a purely microbial one. The disease if limited to the upper or gingival third of the tooth, especially of a single root tooth, is said to be curable, but if it is found that the middle or apical third of the tooth is diseased the prognosis is very unfavorable.

The hemorrhages and the other symptoms referable to the local condition indicate that the gums are extensively infected, but it must not be lost sight of that tartar will predispose to pus formation, and all cases where this condition is present should not be termed pyorrhea alveolaris. A person's mouth that is not cleansed or brushed regularly; one where the teeth are closely applied; where deformities of the teeth are present or overlapping in some instances, all of these conditions make it possible for the accumulation of bacterial life, food particles, tartar and desquamated cells, all form a nidus or even a pabulum for the multiplication of the flora of the mouth. Granting that the flora is mostly of the nonpathogenic type of bacteria or microorganisms, it is the number of bacteria and not their types that bring about a condition of sepsis.

Just exactly as the accumulation of bacteria in meats or food products tends to produce poisonous end products, though not all disease producing in themselves, the absorption of these substances gives us the symptoms of meat poisoning.

So it is in an unclean mouth: The bacterial flora in a clean mouth is comparatively slight, while in a mouth which is very rarely or occasionally cleansed by mouth wash or brush, or both, is simply swarming with bacterial life. The bacteria found in the mouth without decayed teeth is not nearly so numerous as where this condition exists in addition.

Various forms of cocci, bacilli, spirilla, and leptothrixes make up the usual content, but in others, pneumococci, streptococci, and diphtheroid organisms are found in addition to the above.

Spirilla of various types are present where decay is found, but in the dentinal tubules the long threads of the leptothrixes and sometimes streptothrixes are found.

Personally, I believe that the ingress of bacteria into the blood stream does not very often occur from decayed teeth or diseased gums. What does occur far more frequently is absorption of the products of the bacteria, either the nonpathogenic or pathogenic forms. In other words it is to the toxigenic bacteria that most symptoms are due, or auto intoxication.

Systemic phenomena which are absolutely toxic in nature can, I believe, be often traced to a septic condition of the mouth.

The headaches, the flushes of heat, pain referable to the eyeballs, sometimes slight or pronounced fever, malaise and other vague symptoms, chills or pronounced rigors can very easily be traced in some cases to the condition of the teeth and mouth. The gastric disturbances, the intestinal disorders, with apparently no cause from errors in diet, can be due to the continual swallowing of products of putrefaction and decomposition going on in the mouth as a result of accumulated bacteria and their products.

Apart from the symptoms referable to the stomach and intestines, it seems reasonable to suppose that other viscera may suffer from the intoxication. It is well known that Hunter, our English colleague, believes that Bright's disease, mucus colitis, and even sclerosis of the spinal cord and joint affections may occur from oral sepsis as well as many instances of general malnutrition.

In some cases of profound anemia, resembling in its blood picture pernicious anemia, symptoms referable to the stomach and intestines are very common.

It is possible that the condition of the mouth with its products of decomposition play a part in the alteration of digestive ferments, and thus bring about improperly prepared and improperly masticated food for gastric digestion.

Another point in oral sepsis is abscess formation. I do not refer alone to the abscess a dentist finds at the root of a tooth, almost milliary so to speak, but a lesion occurring which sometimes attains the size of a pigeon's egg or larger upon the jaw. It should be a matter of routine to the physician or surgeon, that where an abscess occurs in this region an examination of the teeth should be made in each case, to exclude, if possible, decayed teeth.

The first point regarding prophylaxis in my mind is a proper cleansing and brushing of the teeth to rid the mouth of particles of food and accumulated deposits of desquamated cells with entangled bacteria.

I believe that proper brushing of the teeth with some scientific tooth powder, then rinsing the mouth with some alkaline wash as the liquor antiseptic of the United States Pharmacopæa, diluted about three or four times with water, is extremely efficient in keeping the oral cavity clean. Hydrogen dioxide is also extremely useful, but should not be used too generally where cavities exist.

If this brushing and rinsing are indulged in twice or thrice daily, the mouth, if the teeth are intact, should be perfectly clean.

The benefit that is derived from cleansing the mouth can in some instances be very quickly no-
ticed, and by a bacteriological examination the flora is a much different one as well as a lighter one.

If, however, there is the first sign of decay or soreness of the gums, the advice of the dentist should be sought, and treatment at once instituted to save as much as possible, for no one knows how valuable the teeth are until he loses them. Sometimes ulcerations upon the lips or gums are cured by many of the simplest home remedies, yet in other cases prolonged ulcerations will only respond to the most strenuous treatments.

Where decay is noticed to run an especially rapid course, no capping nor even filling should be resorted to, but immediate extraction urged. Where in the judgment of the dentist capping has been resorted to, it does not seem unreasonable to suggest a rigid examination of these appliances or even removal of them at stated intervals, if they seem to have been improperly applied.

Vaccine treatment—mostly autogenous vaccines—has been used with great success by a number of men in the treatment of pyorrhea alveolaris. Whether this is a permanent cure or not remains to be seen, but where gouty and rheumatic dia- theses are the underlying causes it does not seem that we have yet found the remedy for this affection.

My personal views upon this affection are that the constant formation of pus and discharge which is for the most part swallowed by patients is dele- terious to health. The disease or condition is a progressive one and usually results in loosening and loss of the teeth, so why not advise extraction and substitute false teeth? The looseness of the teeth lessens the proper mastication of food and this in itself is sufficient for gastric or intestinal indigestion or both. As the organisms most com- monly present in the discharge are pyogenic ones, it seems reasonable to suppose that even stock vac- cines may exert some beneficial results, but it ap- pears that the ordinary bacterial flora which are not easily cultivable increases in this disease so that the pyogenic cocci vaccine does not seem in itself to overcome the process.

If a vaccine were made from all the bacteria that are found in this process without trying to isolate the predominant ones, this mixed vaccine might alleviate or even cure the condition. Where in other pyogenic processes there is mixed infection, cures, or improvement occurs where mixed vaccines are used, and not where the most common organ- isms alone are used for this purpose.

Regarding the reaction of the secretion of the mouth irrespective of oral sepsis (using litmus paper as the test medium), the greater number give an acid while others give an alkaline and some a neutral reaction.

Where decayed stumps are present, these should be removed, and where decay is evident in teeth this process should be attended to at once and in- spected at stated intervals.

Whenever soreness of the gums is present follow- ing injury, as from toothpicks or pins, imme- diate attention should be given, as a prostrated infection may be brought about.

JEFFERSON MEDICAL COLLEGE.

A CLINICAL REPORT ON THE VALUE OF TURTLE TUBERCULIN IN THE TREATMENT OF TUBERCULOSIS.*

By the late William J. Beattie, M. D.,
Littleton, N. H.,
Formerly Assistant to Professor Piorkowski in Berlin;
and Edward E. Myers, M. D.,
New York,
Assistant Laryngologist and Rhinologist to Outpatient Department, New York Polyclinic Medical School and Hospital; and Assistant Laryngologist to the Vanderbilt Clinic, Columbia University.

We wish to emphasize the fact that sanitation, hygiene, cleanliness, individual drinking cups, seg- regation, disinfectants, sanitoria, country residence, outdoor dormitories and all other means and mod- ern appliances thus far devised for ameliorating the condition of the tuberculous patient have failed to arrest the onward march of the terrible pale de- stroyer—the great white plague. It would seem that, while all the scientific means enumerated above are good and commendable, there are yet conditions lacking to insure the desired and much longed for results. It therefore behooves the profes- sion to seriously inquire why the progress of the great white plague has not been arrested. This may be readily explained by the fact that the pro- fession until Robert Koch’s discovery of the tuber- cle bacilli were seeing it as were “through a glass darkly.” Since then much progress has been made, as was outlined in our contribution published in the New York Medical Journal, September 13, entitled, Relative Value of Turtle Tuberculin in the Treatment of Tuberculosis. At last science, thanks to the researches of Piorkowski, has given us a specific curative and immunizing agent in turtle tuberculin, and from the combined collective experience of Professor Piorkowski, Doctor Beattie, and Doctor Myers we believe that we are now entering upon a new era in the specific treat- ment of tuberculosis, and that Piorkowski’s turtle tuberculin will prove the foe to tuberculosis that Jenner’s vaccine is to smallpox, and also that the time is not far distant when turtle tuberculin will be used to immunize children against tuberculosis as Behring’s diphtheria antitoxine is now used to im- munize children against diphtheria.

Piorkowski believes that in turtle tuberculin, a remedy is provided which, when injected, intravenously, combines with the receptors, as explained by Ehrlich’s side chain theory, and forms an antitox- ine that acts very much like Jenner’s vaccine, and is especially adapted as a protective inocula- tion. He also avers that all endeavors of thera- peutics in tuberculosis based on Koch’s teachings, which consist of injections of living human tuber- cle bacilli, attain a certain result, but, if accurately judged, while possessing some virtue, fail to exert the curative properties wished for.

Happiness and physical prosperity depend largely upon the health of the people, and without health our nation is wrecked. No thoughtful citizen can contemplate the inroads of disease without a shudder, and more especially if we carefully study the mortality of tuberculosis, one is almost over-whelmed at the thought of its ravages. Accord-

*For further information write to Dr. E. E. Myers.
ing to the United States census report, it is a reasonable calculation that 200,000 people die annually in the United States, of this Great White Plague, which is now a preventable and curable disease. It is conservatively estimated that 1,250,000 people die annually from this disease throughout the civilized world, although an analysis shows that 3,425 die each day, or two and one half every minute, day and night. It is further conservatively estimated that 600,000 school children in the United States, alone, have traces of tuberculosis.

Since the appearance of our article in the New York Medical Journal for September 13, 1913, there have been so many requests from the profession for further information on this subject with clinical reports and results of cases treated, and being physically unable to personally reply to this volume of correspondence, we have decided to offer through the medical press a few clinical reports as a reply to this correspondence, and have gone over our case records and selected four clinical reports, each illustrating a type of tuberculosis, viz.: Case XV, pulmonary tuberculosis; Case XXI, tuberculosis of the knee joint; Case XXVII, tuberculous adenitis; Case XLIV, laryngeal tuberculosis.

Case XV, May 13, 1913. A. S., inspector in the custom house service of the United States government. Aged thirty-two years. No tuberculosis in the family. As a child he had smallpox—otherwise negative.

Present Illness: About September, 1909, suffered from intermittent fever several physicians who diagnosed his illness as cancer of the stomach. At that time he weighed 175 pounds. For three years he remained in a weakened, extremely nervous condition. Weight greatly decreased until he reached 125 pounds. In August, 1912, his weight had further decreased to 100 pounds. He complained of loss of appetite, restlessness, and insomnia. He had had a severe, dry, hacking cough, and later expectorated a large amount of thick, yellow sputum. At that time he consulted Dr. A. R., of this city, who prescribed for him his sputum and referred him to the New York Board of Health, tuberculosis bacilli in the sputum being reported. He was advised to enter a sanatorium at Saranac Lake, which he did. The diagnosis was confirmed by several physicians before he entered the sanatorium. He remained there for three months, at which time he was advised to return to the city for an operation upon his nose and throat, which consisted of removing the tonsils and a submucous operation. He was shortly afterward operated upon for appendicitis. After the operation his weight fell off to 105 pounds, his cough and expectoration increased, and was followed by severe pains in the chest with hemorrhages. He became so weak that he was unable to hold his knife and fork in his hand. In January, 1913, he went to the sanatorium in the Adirondacks and remained there until April, 1913, when he returned to New York city. He then consulted the medical director of a New York tuberculosis hospital who found he had the physical signs of chronic tuberculosis.

Examination: On May 27, 1913, patient was examined by Doctor Beattie and a few days later by Doctor Hyams and Doctor Myers. Inspection showed a man five feet, ten inches tall, sallow complexion, drawn and anxious appearance about the face and muscles and prominent veins. The spaces above and below the clavicles and between the ribs were greatly increased in depth. Expansion over both apices deficient, especially over the left one. Auscultation showed coarse crackling rales, increased voice and whistle, increased tactile fremitus, prolonged and harsh expiration. Weight 125 pounds, pulse 108 standing, fair tension and volume, respirations 24, temperature 106° F.

Diagnosis: Pneumonitis, left, chronic, secondary stage.

TREATMENT: He received his first injections on May 26, 1913, and in the first week in June and at various intervals thereafter until about the middle of July, when he went to the White Mountains where he was treated by Doctor Beattie. All told, he received eight injections. September 1st he returned to New York city. Examination by Doctor Beattie, Doctor Hyams, and the medical director of a tuberculosis hospital, and Doctor Myers, showed that all his previous subjective symptoms had disappeared. Examination of the sputum was negative. His weight was 159½ pounds, pulse 72, temperature 98.2° F., no cough, no expectoration, no pains in the chest. He felt strong, and his appetite was good.¹

Summary: Here was a case which had been diagnosed by several competent, well known physicians who presumably are well acquainted with the technic of making a diagnosis of tuberculosis, some of whom are specialists in physical diagnosis. All evidences of tuberculosis of the lungs were present, both physical signs and symptoms. In less than four months after having received Piorkowski’s turtle tuberculosis treatment, we presented a patient who was undoubtedly a pronounced cure. In that short space of time more had been accomplished for him by this treatment than all other known methods for the treatment of tuberculosis extending over a period of three years, as was evidenced by the disappearance of all symptoms and physical signs. It is a noticeable fact that this patient had increased remarkably in weight, without any special efforts to accomplish this result.

Case XXI, May 24, 1913. M. M., a white girl, aged seven years, born in the United States, resides in New York city.

Family History: Father, two sisters, and one brother died of tuberculosis of the lungs. Mother, one sister, and a brother alive and well. Otherwise negative.

Previous History: Whooping cough at the age of five years.

Present Illness: Patient was brought to our office by her mother on May 24, 1913, with the following history: Two years previous the child’s mother had noticed a swelling of the right knee joint. A few weeks later the mother noticed that the child limped and complained of some pain in the joint, and after a few months motion of the joint was considerably restricted. No treatment was instituted for some time, the mother caring for the child herself. She massaged, ointments, and other home remedies. Then she took the child to several of the specialists of the different parts of the joints. The physicians there diagnosed the condition as tuberculosis of the right knee joint. Plaster casts were applied, followed by a steel brace which she was still wearing when brought to us. The child never had cough, hemorrhage, or night sweats.

Examination: By Doctor Beattie, Doctor Hyams, and Doctor Myers showed on inspection a fairly well nourished child, good color, head, neck, and chest negative. Right knee joint showed a fusiform swelling with limited motion. Flexion not possible beyond ten degrees, with slight muscular spasm. The patella was adherent, and quadriceps extensor muscle was atrophied. Measurement of the right knee with a steel tape over bicondylar crest of the patella was 10½ inches; over tibia, 8½ inches. No heat or redness about the joint. Kidneys and abdomen negative. Temperature 98.4° F., respirations 18, pulse 84, good tension and volume. Weight forty-two pounds.

Von Pirquet test positive.

Diagnosis: Tuberculosis of the right knee joint.

Treatment: On May 26, 1913, at 10:45 a. m., one minim of Piorkowski’s turtle tuberculosis was injected into the buttoc. The patient was seen about six hours later, and it was observed that the temperature had risen to 99.6° F., and her pulse to 96. The following day, examination of the site of injection showed a slight infiltration with a minute reddish papule at the point of injection. Patient felt slight languor or general feeling of unwellness. She received seven injections all told. At first every seven days...
days, but interrupted in July and August twice on account of short vacations of ten days each. Examination on September 19, 1913. Her weight was forty-eight pounds, three ounces. Leg could lie flat on the thigh to right angle. Measurement over centre of the right patella was nine inches, over the left 8½ inches. Her color was good; appetite good; slept well, felt strong, bright, and cheerful and felt better in every way.

Summary: In a brief period of less than four months motion of the affected joint was increased fifty per cent more than was accomplished in the previous eighteen months in the hospital for joint diseases. The swelling of the knee joint had been reduced one half inch; the patient had gained six pounds, three ounces. She had good color and good appetite, slept well, and general improvement in every way was noticeable.

Case XXVII. Miss G. S.; white girl; aged nineteen years; born in United States; residence, New York city; occupation, stenographer.

Family History: Father died of sunstroke at the age of forty; mother died at the age of thirty-three years of typhoid fever. One sister was living in good health; one sister had died of measles and one brother had died of diphtheria, both in infancy. No history of consumption in the family.

Present illness: Patient had complained of pain in joints for a long time, but never had noticed any swelling. About one year ago, he had suffered from headache, and there were hemorrhages, aches, and pains in the chest. The patient had been advised to return to the hospital again and undergo a second operation. The wound remained open until September, 1911, during which time he was an- nouned two or three times large portions from a sinus. In March, 1913, these glands had progressively enlarged and began to suppitate again discharging a thick yellowish watery fluid. A microscopical examination of this fluid was negative. For the past three years, the patient had had persistent night sweats, hemorrhages, coughs, and expectoration. Examination of the sputum was negative.

Examination: Inspection showed a well nourished girl, good color with a large, irregular swelling of the cervical glands. The patient had not been living a healthy life. There were numerous small hemorrhages in the supraclavicular fossa, and extending behind to the suprascapular fossa. On palpation several hard, irregular glandular nodules were found along the side of the neck in the area mentioned above, ranging in size from a five cent piece to that of a silver dollar. Some of these glands were isolated and freely movable, with depressions between them, others were adherent to the skin. About an inch below the ear, one of these glands had softened, broken down, and left a sinus about the size of a goose quill, from which there poured an ichorous discharge. Lungs, heart, and abdomen negative. Temperature at 6 p. m., 99.2°F.; pulse, 81; regular, good ten- sion. Respiration, 20. Diagnosis: Tuberculosis of the left side of the neck.

Treatment: On May 26th, she received an injection of two minims of turtle tuberculin in sixteen minims of normal saline solution. The following day, May 27th, she did not feel any ill effects from the injection, except a slight languor. The pulse rose about six hours afterward to 96, temperature 99.5°F. An examination at the point of injection on the afternoon of the same day showed a red dish papule with a minimum amount of infiltration. The patient received injections of two minims of turtle tuberculin every seven days for about three weeks, at the end of which time the discharge stopped, the sinus closed, and she had increased in weight (on June 15th) from 102 pounds to 111½ pounds. After that date she received about four injections with occasional interruptions on account of her going on short vacations. On September 19th, her weight was 111½ pounds; pulse, 80; standing temperature, 99.6°F. Examination showed only a few, small glands, where formerly had been a large irregular mass of glands with a discharging sinus. At that time there was no discharge nor sinus, and on inspection the neck, to all outward appearances, was practically normal.

Summary: This case illustrated the fact that in a brief period of less than four months, more improvement had been effected from the administration of Piorkowski's turtle tuberculin, than in more than three and a half years of treatment by surgical intervention and other methods of treatment. During this period there was a gain of eight pounds, with an increase of appetite, and the patient felt strong and well.

Case XLIV. July 23, 1913. M. M., aged forty-four years; lived in Brooklyn, N. Y.; born in Ireland; occupation, stenographer.

Family History: Father died at age of seventy years of heart disease, mother at age of sixty-five years, cause unknown, one brother at age of twenty-four years from pneumonia; three sisters were living. One sister had died at age of thirty-three years, cause unknown.

Previous History: Had had influenza twenty years ago.

Present Illness: For past five years he drank from ten to fifteen minims of spirits daily, and has used tobacco or drugs of any kind. About eight months ago, he had a cough followed by pains in the chest. Noticed that his appetite was failing. His weight at the time of the first examination was 167 pounds, while his normal weight had been 180 pounds. Seven months ago he began to have nightsweats which continued up to the present time. About five months ago he began to expectorate a thick yellowish sputum which later became mucopurulent and was particularly profuse at night; a few hemorrhages. He had not complained of dyspnoe, remained strong, and was tolerably well, only suffering from occasional hoarseness and complained of considerable hoarseness. We first saw the patient in the hospital on July 16, 1913, where he was sent to us by the medical department for a throat examination.

Examination: Examination of the larynx by Dr. E. W. Kobler and Doctor Myers revealed pallor of the epiglottis and infiltration of the left arytenoid. The vocal cords were slightly congested and covered with a sticky, profuse mucus. The changes were not extensive. There were no signs of ulceration of the left apex and supraspinous fossa and in front extending down to the sixth rib, and toward the left as far as the midaxillary line. There was increased tactile fremitus over the left apex and supraspinous fossa. Increased voice and whisper, reduced heard over the right apex and numerous moist rales at the left apex and beneath the clavicles as far down as the second rib. No cavities. Abdomen negative. The urine contained four percent of sugar.

Diagnosis: Tuberculosis of the larynx, tuberculosis of the left upper lobe, secondary stage, complicated with diabetes.

Treatment: On July 17, 1913, microscopical examination of the sputum made by the New York Board of Health showed tubercule bacilli. On July 23d, one minim of turtle tuberculin in sixteen minims of salt solution was injected. August 1st, one minim of turtle tuberculin was injected. Temperature, 100.8°F.; pulse, 86; respirations, 24. About twelve hours after receiving the injection, he felt slight languor, with loss of appetite. His temperature rose to 100.6°F.; pulse was 108. At point of injection a minute red papule was noticed. A decrease of expectoration was noticed and patient felt better and stronger, hoarseness less, distressed feeling of larynx much diminished; weight 169½ pounds. On the following dates, August 15th and 22d, September 3d, 10th, and 15th, one minim of turtle tuberculin was in each case given. On the latter date, physical signs of the chest showed improvement, especially as far as rales were concerned. The cough was scarcely noticeable during the day; hemorrhages no longer present; no pains in throat or chest; color of the sputum whitish. At the last injection, the temperature was 99.3°F.; pulse, 108; respirations, 104; weight, 166½ pounds. An examination of the larynx showed slight pallor of the epiglottis, infiltration of the affected arytenoid practically gone. Con-
gestion of the cords scarcely noticeable, and a very slight amount of mucous on the cords; patient felt stronger: much more comfortable especially as to cough, expectoration, and hoarseness.

Summary: I cite this case more particularly to bring out the laryngeal tuberculosis than the condition of the lungs. Here is a patient who had been hoarse for some months, and in the brief period of a little over a month the hoarseness had gradually disappeared. The signs were practically absent in the larynx, and there was improvement in so far as cough, expectoration, and color of sputum were concerned. The patient had practically retained his weight, although the tuberculous condition was complicated with a severe form of diabetes. Under tuberculin treatment in this short time he had improved more than the previous eight months under other forms of treatment.

418 Central Park West.

TESTING URINE FOR INDICAN.

BY JACOB ROSENBLOOM, M.D., PH. D., Pittsburgh, Pa.
(From the Biochemical Laboratory of the Western Pennsylvania Hospital.)

After considerable experience in testing urine for indican the writer has noted some points which he thinks might prove of value to other workers. The procedures for the detection of indican in urine are based on the liberation of the acid from its base, on the oxidation of the indoxyl sulphonic acid or urinary indican into a colored product, and the solution of this substance in a suitable solvent.

It is to be remembered that if an excess of the oxidizing agent is added that the color will be destroyed and also that the tube in which the reaction is carried out must not be vigorously shaken, otherwise the chloroform becomes emulsified with the urine, from which it will separate with great difficulty, if at all.

After trying all of the various tests that have been used for the detection of indican, I have arrived at the conclusion that Jaffe's test as modified by Obermayer when certain improvements described in this paper gives the best results.

This test is best carried out as follows: 1. To nearly one half test tube full of urine add an equal bulk of concentrated hydrochloric acid containing four grammes of ferric chloride to the litre. Mix by pouring from one test tube to another, not by shaking the tube, as this is apt to emulsify the urine with the chloroform. Allow to stand ten minutes and then add from three to five c. c. of chloroform. Mix again by pouring from one test tube to another and allow to stand for fifteen to thirty minutes. The supernatant fluid above the chloroform extract is now poured off and the test tube is filled with water. The marked change in the character of the chloroform extract on the addition of the water is very striking. One often finds that the chloroform extract has a dirty grayish green color, but on decanting the supernatant fluid and adding water the chloroform extract becomes a pure blue.

I have also found that in urines that have been preserved with thymol the chloroform extract obtained in this test has a violet color, thereby interfering with the action. An apparent increase in the excretion of indican was observed by Bohland when large doses of thymol were given, but as thymol appears in the urine as thymol sulphonic thymol glucuronic, and thymol hydroquinone sulphonic acids and as a chromogen of a green pigment, Blum was able to show that the color obtained by Bohland was not indican, but a derivation of thymol. The interfering action of thymol must be borne in mind especially as it is a common procedure to use this substance as a preservative for urine. The color due to thymol resembles the violet color obtained in the chloroform extract when potassium iodide is present in the urine. The violet color due to thymol as well as the violet color due to iodide disappears on the addition of sodium hydroxide or of sodium thiosulphate.

It is also to be remembered that if any protein is present in the urine, it must be removed by boiling and precipitating the protein by means of dilute acetic acid and then using the filtrate for the indican test, as protein yields a blue color with concentrated hydrochloric acid.

5659 Beacon Street.

INTRAVENOUS INJECTIONS OF THEOBROMINE SODIUM SALICYLATE.

Preliminary Communication.

BY SELIAN NEUHOF, M. D.,
New York.

Adjunct Attending Physician, Lebanon Hospital.

Theobromine sodium salicylate, a purin derivative, is an amorphous, hygroscopic, white, odorless powder, salty and slightly alkaline to the taste. Its chemical formula is: C_{7}H_{8}Na_{2}O_{4}C_{9}H_{6}OHCOONa. Though its mode of action is still in dispute, there is abundance, clinical, and experimental evidence of its diuretic effect. When given experimentally, intravenously, or intramuscularly in lethal doses, the animals die with symptoms of central paralysis and in a condition of muscular spasm. It is official in the German pharmacopoeia as theobrominum nitricosalicilicum.

The only book on clinical diagnosis mentioning this fact is Emerson's edition, 1860, 185, who states, however, that the urine is bluish green, but this may apply only to the thyphol extracted as a conjugated substance and not to thymol existing free in the urine.

Deutsche medizinsche Wochenschrift, 1860, No. 16, 1910.

Theobromine sodium salicylate was first introduced by von Schroeder, 1, 2 by whom its effect upon the kidneys was ascribed to irritation of the renal epithelium. As the result of more recent experiments, Loewi 3 maintained that its primary effect was vasodilatation and increased renal circulation, and the secondary effect increased diuresis. The clinical fact that theobromine sodium salicylate may sometimes be given continuously for weeks and months with benefit seems to support the view that at any rate it does not always produce renal irritation. Besides its diuretic effect, a number of observers have shown clinically and experimentally that theobromine sodium salicylate also increases the proportional output of nitrogen, of sodium chloride, and some of the other solid ingredients of the urine.

The recent careful study of the kidney's means of functional tests 4, 5 and blood pressure observations, the experimental production of different types of nephritis and the as yet only partly successful attempt to correlate the foregoing data with clinical findings show that the whole subject is at present unsettled. The undoubted value of theobromine sodium salicylate in edemas accompanying cardiovascular renal disease and in some types of primary kidney lesions has induced me to attempt its intravenous administration. This method seems of importance because the drug is particularly indicated in uremic conditions with vomiting, delirium, and disturbances of the sensorium in which it cannot be given by mouth, or if so given, the amount absorbed is very slight or nil.

In 1912 I gave theobromine sodium salicylate intravenously to four patients; three were cases of cardiovascular renal disease, the fourth was one of probable tubular nephritis. One of these patients who had had extreme general anasarca for several weeks prior to the injection was temporarily improved. The method then pursued was to inject ten grains dissolved in 200 c.c. of water once or twice a day. This method was discarded because it was too cumbersome and did not admit of sufficiently frequent administration. At present five per cent. solutions are employed, the percentage ordinarily used in animal experimentation. In two cases reported by Ardelby 6 this percentage was also used. Pharmacological examinations 8 show that the specific gravity of a five per cent. solution at 20° C. is 1.0228 and its alkalinity is equal to that of a 2.4 per cent. solution of sodium bicarbonate. Sodium bicarbonate of this concentration or even stronger is sometimes given intravenously in diabetic coma. A five per cent. theobromine sodium salicylate solution heated in a closed vessel at 90° C. for one hour, again for one hour, and then for one half an hour shows slight yellowish discoloration and a very slight loss of alkalinity, but remains perfectly clear. Thus sterilization does not alter the solution. The usual dose employed was one gramme, i.e., twenty c.c. of the five per cent. solution. In one instance two grammes (forty c.c. of the solution) were given at one time. The solution was sterilized by boiling immediately preceding injections. If the entire solution entered the vein, there was absolutely no local reaction. If a few drops found their way into the subcutaneous tissue, some induration, ecchymosis, or slight pain lasting a few days sometimes followed. In one instance, through error, the solution was injected subdermally; a local skin slough and ulcer resulted. The injections were never followed by systemic reactions.

Thus far the five per cent. theobromine sodium salicylate solution was given intravenously in the following three cases:

CASE I. Female, aged fifty-nine years. Diagnosis, nephritis, myocarditis, uremia, hemiplegia. The patient was stuporous at times. Two injections were given, one intravenously without any local reaction; the other was injected subdermally and was followed by an ulcer as already mentioned.

CASE II. Female, aged twenty-two years. Diagnosis, acute (tubular?) nephritis of unknown etiology. She had edema of the legs. The urine contained albumin and casts and the heart was apparently normal. The systolic blood pressure, taken daily, averaged 135 mm. Hg. The phenolsulphonephthalein tests, repeated several times, showed an average output of twenty-five per cent. at the end of two hours. The normal is about sixty per cent. She was given Karell diet (1000 c.c. of milk daily) for two weeks. For several days four grammes of salt were added to the diet in order to study the salt elimination. Twenty c.c. of a five per cent. solution were injected intravenously in each arm every third day: this procedure was repeated four times; no effect upon phenolsulphonephthalein or salt excretion was noted. There was no clinical improvement.

CASE III. Female, aged forty-five years. Diagnosis, cardiovascular renal disease. Her illness began eight months ago. Her complaints were palpitation, precordial angina, and severe headache. She had prethelial edema. The specific gravity of the urine was 1.010 and contained a few hyaline and granular casts. The average systemic blood pressure was 210 mm. Hg. Several phenolsulphonephthalein tests showed an average excretion of twenty per cent. in two hours. On three occasions every third day the drug was injected intravenously. The injection had a marked diuretic effect, there was no effect upon blood pressure or phenolsulphonephthalein excretion. The patient improved, but it is difficult to state how much rest and diet contributed to the improvement.

The object of this communication is to show the practicability of intravenous theobromine sodium salicylate injections. The solution is readily prepared and sterilized, and when properly given produces no reaction. While twenty c.c. of a five per cent. solution have been found a convenient standard, it may be modified to suit individual requirements. It seems particularly indicated in uremia, in the anuria of cardiovascular renal diseases, and in some types of primary renal disease when internal administration is impracticable or impossible and quick diuretic action is necessary. It is further suggested that these injections may be of benefit in some types of uremia accompanying eclampsia; in conjunction with other forms of treatment, it may help in starting diuresis.

My thanks are due to Doctor R. Stein and Doctor A. Mayer, attending physicians, who have placed their patients at my disposal, and to the house staff for its active cooperation and assistance.

1275 Madison Avenue.

SKIN DISEASES IN SCHOOL CHILDREN.*

By Edward Pisko, M.D.,
New York.

Not having read the transactions of the three previous congresses, I do not know whether the subject I am about to submit has been called to your attention heretofore; but whether it has or not, the subject is of sufficient importance to be urged repeatedly, with the hope that it may result in action.

Great progress has been made in school hygiene by improved school buildings. Millions upon millions are being spent to make the buildings look inspiring. The public has at last realized the importance of developing the child physically, and most schools have been fitted with gymnasiums. But the most important of all, the danger from diseases of the skin in children, and from the speed with which they are transmitted to others, has been overlooked. A great many mothers are as ignorant to-day of the great dangers underlying and resulting from skin eruptions and diseases as they were a century ago. But we cannot blame the mothers when some of the city authorities, men of education and high standing, display no greater knowledge.

How many realize the great injury to the physical wellbeing of the child in the common contagious diseases known as scabies, pediculosis, ringworm, etc.? Do they know that in the absence of proper and scientific treatment the parasites multiply by the millions and that they are transmitted to other children with greater speed than many diseases for which there exists public horror, let alone the loss of school time on the child and the consequent increase of school work forced on it upon its return, in most cases beyond the child's capacity?

And yet, excepting the institution at Randalls Island, with which I am connected, where 1,700 children with skin diseases are treated and cared for by competent physicians and nurses while they attend special classes, the nearest approach toward minimizing the danger to our children at school from contagious diseases of the skin is the superficial examination of the children by some incompetent and inexperienced physician who gets a salary equal to about one half that of a bricklayer.

It is mostly only in advanced stages that the various skin diseases are discovered by these young physicians, and the children are then sent to public skin clinics, where not enough time can be given to the treatment in the hour or two that the skin clinics are open, and where, because of the commonness of the diseases, they are treated with no special care by the physician or his assistants in charge.

I do not say this in condemnation of the physicians in charge of the clinics, but I am speaking of actual existing facts based upon my experience of over twenty-five years in the public skin clinics of New York. Undoubtedly another cause for the lack of care in the clinics is the fact that the physicians receive no compensation or return of any kind.

It is not enough for the child to receive a hasty examination in the clinic and then be sent home with a prescription and in that way merely transfer the infection from the school to the home and the neighbors' children. There should be specially trained nurses in charge of districts, who should visit the households, study the family conditions, execute and administer the treatment prescribed, and supervise the sanitary conditions of the home. Only in that way will the spreading and infection be reduced to a minimum.

There are mothers' clubs, women's protective leagues, social committees, and all sorts of women's societies; but here is a large field which for real public good all of the other societies together pale into insignificance.

A very common appearance in the clinics is the "sore arm" resulting from bad vaccination. I only mention this casually to indicate the chaotic conditions existing. A young physician gets an order to vaccinate fifty or sixty children. The report must be returned within the given time of a few hours. What happens? The physician administers the vaccine and hands in the report. His interest is not in the children but the report. No care was taken in the preparation of the children for the vaccination; and injections were made as though the children were to develop into horses rather than our future citizens. The infectious arm keeps the child out of school from three to five weeks, during which time it runs around in the streets, associates with all kinds of degenerates, and has its morals and habits corrupted.

As an illustration, some four years ago a boy of twelve was sent to my clinic at the Harlem Hospital with a ringworm of the scalp. Being barred from school for months, he joined the army of our famous younger and older corner loafers. Sometime thereafter he returned complaining that he was hardly able to walk. On examination, the anal region was found studded with large, moist papules, an eruption covering the whole trunk and the initial lesion of syphilis about two inches within the rectum. The boy confessed that a gang in the neighborhood abused him and a number of other boys in the same way. I succeeded in getting hold of another similar case of a boy of twelve, who was home from school on account of scarlet fever in his family, and presented both cases before the Manhattan Dermatological Society at the March, 1900, meeting.

I do not criticize the board of health. I condemn those who will cut the budgets for schools and hospitals in favor of civic centres. We are not prepared for a civic centre until we show civic pride in the development of our future citizens.

The physicians in the police and fire departments are paid well and forbidden to engage in private practice; why not the same in the board of health? Make their number of physicians adequate. Let their salaries be commensurate with their ability. Let efficiency be the standard. To permit a young and inexperienced physician to do school work, by spending a few hours at school, in blissful igno-

*Read at the Fourth International Congress on School Hygiene, held at Buffalo, N. Y., August 21-30, 1913.
ance, is not only a farce but an unpardonable crime toward our future generation.

It is a well known fact that outside of infantile eczema, especially intertrigo in the folds of the neck, the anal and the genitocrural region, almost two thirds of the skin diseases, including the acute infectious diseases, the eruptive fevers such as chickenpox, measles, and scarlet fever, are seen in school children; naturally so, because of their contagiousness and the facilities for spreading.

The three greatest enemies of school children are pediculosis, scabies, trichophytosis—all three highly contagious and rapidly spreading at the house and in the school. It is not within the scope of this paper to give the clinical picture and pathology of these diseases; but I want to outline a very practicable and inexpensive treatment and an effective cure. While it is almost immaterial which of the antiparasitic remedies are used, it is essential how they are used, and I have therefore advocated the institution of district nurses. It is not enough to smear the sulphur ointment in a case of scabies; no such patient will be cured, and the whole family will get it. The preparatory bath in a tub of hot water and the use of a scrubbing brush with a lot of soap must cleanse the body first, all underwear and bed linen must be washed and boiled. In pediculosis the best and safest remedy is the old standby, kerosene. It kills the lice and nits, but it must be done correctly. In spite of the offensive odor, the head must be washed with it repeatedly and kept covered, no sores will occur, and within a week or so the children will be able to go to school again. In ringworm, X ray is the ideal treatment, but if not available the scalp must be shaved every week and a strong antiparasitic p-a-t-e, preferably an ointment of the red oxide of mercury, should be applied. But above all a competent nurse is most essential.

I am using the plainest of English so as to be understood by everybody, as I consider it of vital importance for the future generation. Every taxpayer should be advised of the conditions and dangers, and he should protest against the cutting of the budget in the direction outlined. In this way the standard of school hygiene will be raised.

I hope that this paper is brought to the attention of the proper authorities, and if it only awakens some interest its mission will be fulfilled.

Here is a large field not only for the fathers of school children, but also for those who are members of this congress and have the interest of real school hygiene at heart.

Let us not forget for one moment that the future citizens are formed in our public schools and that it is not enough to teach them hygiene as a subject, but as a real, practical hygiene, in order to enable them to take care of themselves, and thus become strong and healthy men and women. Prevent the school from being the breeding ground of disease. No expense in this direction should be spared. Any innovation, if good and practicable, should be applied and installed at once.

Sanitary perfection is the only safeguard against all communicable diseases and epidemics. "Mens sana in corpore sano."

THE DIFFERENTIAL DIAGNOSIS OF SOME ORDINARY EYE DISEASES.*

BY F. KRAUSS, M.D.,
Philadelphia,
Ophthalmic Surgeon to the Protestant Episcopal Hospital, Ophthalmic and Aural Surgeon to the St. Christopher's Hospital for Children, etc.

One of the difficult problems facing the general practitioner is the recognition of ocular diseases. It is not the good fortune of everyone to be compelled to study diseases of the eye. Therefore to many it is a terra incognita which is naturally considered abstruse and uninteresting.

In a short paper I can open the door but slightly, but if this little aperture will help the vision and understanding of some one in the audience, I will feel that my labor has not been wasted. I will arrange this discussion in two sections: First, eye diseases showing external symptoms, and second, those showing disturbed sight with no external lesions.

 Conjunctivitis or pink eye as it is familiarly termed assumes many types due to the virulence of the organism and the susceptibility of the patient. In general it can be recognized by the fact that there is a discharge of secretion which may be pus, mucopurulent, or mucus, or from the eye, causing the lids to adhere after a period of closure, as for instance after sleep. When the secretion is small in amount and mucoid in character, it is a simple catarrh. When quite free and heavier in type, accumulating in the inner corners of the eye in yellowish or yellowish green masses, it is the familiar contagious mucopurulent conjunctivitis or the real pink eye. When the lids are very edematous with copious discharge of pus, it is gonorrheal in type and probably due to the Neisser organism.

 Conjunctivitis in a newborn baby appearing before the third day is practicably certain to be specific, and is rapid in its progress if the patient is susceptible. We find cases, however, showing simply a protracted mild catarrh, in which the Neisser organism is predominant in the discharge. In some forms of catarrh there is an additional redness of the margin of the lids. It is in this form that the zinc salts are particularly efficacious.

 Trachoma, sometimes called granulated eyelids, is distinguished by evaginating the upper lid, when the lid is found to be covered with many elevations, frequently resembling a granulating ulcer in appearance and color, at other times being quite pale. The particular point to remember is that the disease is a catarrh very chronic in type, and should be looked for in every case presenting a history of chronic catarrh. Mild cases show the granules in the fornix only. In later cases much scar tissue is seen when the lid is evaginated. When the lathy speaks of granulated eyelids, they usually mean some form of blepharitis, and not trachoma.

 Tuberculous conjunctivitis and keratitis are very common in childhood, and include a large portion of the cases formerly termed scrofulous conjunctivitis or phlyctenular disease of the eye. These patients react strongly to the von Pirquet test, the
ocular condition also being increased primarily by tuberculosis injections. They are chronic in character with acute exacerbations, relapses being quite common. They respond to tuberculin and general tonic treatment with careful diet, bathing, and fresh air. The seashore has not proved beneficial in a great number of these cases. In the phlyctenular types there are roundish red areas on the conjunctiva, especially near to the cornea. They are sometimes accompanied by much photophobia, especially if the cornea is invaded. It is diagnostic of phlyctenular keratitis in children that the patient hides its face in its mother’s dress refusing to lift it even for an instant. In this case forcible separation of the eyelid is necessary. Great care must be exercised, however, as the cornea may be ulcerated to the penetrating point. A slight pressure on the eyeball may cause prolapse of the iris. It is not necessary to place any pressure on the eyeball in separating the lid if care is taken to lift back the lids with the thumb and forefinger of the hand nearest to the eye to be examined, pressing the retracted lid upon the bony wall of the orbital edge. The child must be held on the lap of an assistant in such a way, that the feet and hands can readily be held firmly while the head rests between the knees of the surgeon, who has protected himself with a towel, especially if he wishes to flush the eye.

Corneal disease is easily recognized by the loss of transparency in some of its extent. In ulcers the areas of opacity are usually discreet. When the entire cornea is more or less involved with a more or less uniform opacity with areas of intense vascular congestion, it is more likely to be interstitial keratitis suggesting hereditary syphilis. When the eyeball is intensely red, having at times a purplish zone about the cornea, with slight or no secretion, you must dismiss conjunctivitis from your mind. The deeper structures are affected. The iris if compared with its fellow is seen to be different in texture and color, the pupil contracted, and the eyeball is very painful to the touch. The patient tells you he awakens in the morning with intense pain which is relieved by hot water applications. Iritis differs from glaucoma in that glaucoma presents a steamy cornea with dilated pupil and with the eyeball very hard rather than very tender. The tension can readily be ascertained when compared with the normal eye of a bystander. The iris is not discolored, but appears to be pushed forward, showing a shallow anterior chamber. The intense ciliary congestion is absent.

When in the course of a child’s illness, a squint develops, it may be due to a large degree of latent hypermetropia becoming manifest, but is more likely to be due to palsy. For some reason when a single nerve is attacked, the sixth nerve is probably the one to be most likely affected in toxic neuritis, causing internal squint. The third nerve when affected, causes loss of accommodation, therefore an inability to read.

In the second section of my subject we reach the eye disease showing disturbed sight with no external lesion. For a proper diagnosis we are dependent in these cases on the ophthalmoscope. When the exterior of the eye is apparently normal, except that the pupil is occupied by a greyish re-
conform to a general rule. But in eye diseases, as in other branches of medicine there are many exceptions to all rules, the thorough knowledge of which makes the specialist.

1701 Chestnut Street.

A PLEA FOR MORE INTENSIVE MERCURIAL MEDICATION IN SYPHILIS.

By M. Zigler, M.D.,
New York,
Instructor in Genitourinary Surgery and Veneræal Diseases, Post-graduate Medical School and Hospital; Chief of Clinic of Genitourinary Surgery, Lebanon Hospital; Assistant Dermatologist, Lebanon Hospital; Out-patient Department.

Before the introduction of salvarsan in our therapeutic armamentarium against syphilis, the results obtained by the use of mercury and the iodides were considered marvelous by our professional confrères, but since that date our colleagues have, it seems, suddenly forgotten the efficacy of one of the most potent drugs in our pharmacopœia. This is due to our exaggerated enthusiasm for the new arsenical preparation salvarsan. It has been ever thus, when some new preparation attracts our attention we are apt in our enthusiasm to temporarily discard older therapeutic measures, until a more thorough and searching trial relegates the new treatment to a subordinate position. There is absolutely no doubt that at the present time we are over-enthusiastic regarding salvarsan, not that I would dare gainsay that the results in some cases are truly marvelous, but not more so than with mercury, in proper dose and by proper methods of administration. We were led on to this extreme by Dr. Paul Ehrlich, who stated that the drug was a powerful spirillocide in animals and would probably prove to be the same for Spirocheta pallida in the human. In fact he considered it to be allpowerful against this spirillum, so much so that one large dose could kill all the spirilla, in other words, a "magna therapia sterilis." This false sense of security resulted in many patients receiving, and doctors administering, one dose of salvarsan, and then sending their patients on their way rejoicing, with the assurance that they were cured. In fact, very soon patients, who had been reported as cured, appeared at the various clinics with relapses of all of their symptoms. These patients were promptly placed upon large doses of salicylate of mercury, given hydropermally; when upon the symptoms melted away most rapidly and, what is more important, patients remained symptom free for the entire course of treatment, with few exceptions, and these alcoholics, etc.

A little later it was conceded even by the Germans that several injections were necessary for a cure. What is the opinion to-day? Most authorities are agreed that a number of injections of salvarsan are necessary, but that mercury must be given in conjunction with the same. However, the point I wish to emphasize is the tendency of most men to place too much reliance on salvarsan, and too little on mercury. The latter, a drug which in the presalvarsan days was considered most efficacious, in fact was usually called one of the speciès in our materia medica, is now suddenly cast aside, as not even worthy of our notice, for a preparation which is still more or less in the experimental state. Allow me to quote an example of this; a patient contracted an initial lesion eight months ago. Six weeks after the onset he received the first salvarsan injection, and subsequently in a period of eight months received seven additional injections of salvarsan, and a very few injections of mercury. Wassermann tests made every month after the initial salvarsan treatment were negative. This patient who was discharged as cured by a well known genitourinary surgeon, came East for an opinion. His Wassermann reaction proved to be negative, but from what we know of the course of syphilis, and of the tendency of salvarsan to cause negative Wassermann reactions, which some time later become positive, it certainly is doing a gross injustice to tell the patient that he is absolutely cured. How can we suddenly change our old opinion, that it takes several years at best to cure syphilis, to an opinion like this, whereby the patient is told he is cured after a few injections of a new drug, which most authorities say simply causes a more rapid disappearance of symptoms, but whether it really is a better curative agent than the older drug, it is impossible at present to say. This patient should receive mercurial treatment for an additional year regardless of the absence of clinical signs and symptoms and a negative Wassermann reaction.

If our genitourinary authorities are so enthusiastic, how much more so are our general practitioners, who are influenced by the surgeon’s opinion.

After reading the reports of most syphilographers who have given salvarsan a trial, in a large number of cases, what are their final conclusions? Dr. W. A. Pusey at the American Medical Association annual meeting in 1912 said: “Salvarsan was introduced as a remedy to destroy the infection of syphilis, by one massive injection. What has been its history in the two years since then? First it was given as one large dose of a neutral emulsion, then came the injection of the alkaline solution in the muscle, then the injection into the vein. Now we have salvarsan plus our old reliance mercury. Taking the drug itself, first we had salvarsan, then salvarsan hyperideal, and although one might have thought a drug called hyperideal had reached the acme of its purpose, now we have neosalvarsan, and we have been forced by the sad accumulation of facts away from the claim that salvarsan cures syphilis, except to avoid argument in early favorable cases. The present situation is a far cry from the original idea of a therapia sterilis magna and, yet, the lurking notion of salvarsan as a cure for syphilis is still responsible for a large part of its use. We may say positively, and finally, that salvarsan does not cure more cases of syphilis than mercury does, on the basis of either the physiological or chemical test. I am not prepared to believe from my own experience that, except in unusual cases, the symptomatic effects of salvarsan are more pronounced than those of mercury and iodides in combination. The real problem in syphilis is parasypilis. Arsenic itself has a special affinity for nervous tissue and produces degenerative processes in nerves, and no man can say now, whether these massive doses of arsenic
given as salvarsan are going to diminish or increase them."

Dr. Howard Fox in an article in the Journal of the American Medical Association of this year, entitled The Relative Value of Mercury and Salvarsan from a Serological Point of View, comes to the following conclusions: "In the primary stage of syphilis, especially before Wassermann reaction becomes positive, salvarsan is a most valuable remedy, from both a serological and clinical standpoint. In regard to salvarsan being a most valuable remedy we can say the same for mercury. I have seen a Wassermann reaction become negative, and the initial lesion disappear after two intensive doses of salicylate of mercury, by hypodermatic injection, especially if, in addition, colcemid dusting powder is applied to the lesion. This is by no means an infrequent occurrence. A serological comparison of mercury and salvarsan in the later stages of syphilis fails to show any decided advantage in favor of either remedy."

In consideration of this remark it is one of the greatest mistakes for us to discard mercury or even to give it second place. My plea is for the reinstatement of mercury to its original place, in our fight against the Spirochaeta pallida, and that it should be given in intensive doses by the hypodermatic method. Then, and then only, will good results be obtained in the treatment of syphilis. Salvarsan should be given due trial in every case in conjunction with our chief reliance, mercury. It is much better, as a routine, to give mercury, but if any special indication arises use salvarsan.

Dr. Abner Post, of Washington, concludes in the Journal of the American Medical Association of this year: "We must retain mercury because its usefulness is not diminished in the least, because it can be used when the use of salvarsan is difficult and when it is contraindicated."

Now I shall take the liberty of quoting from the records of several private and dispensary cases, showing the truly marvelous but by no means unusual effects of mercury in intensive doses:

Case. Miss F. H., aged eighteen years: American. Referred to the office by Dr. E. M. Juster, July 22, 1912, gave a history of having had a hard, painless sore on her upper lip for a number of weeks, also hard glands under the jaw. Admitted having been kissed rather promiscuously. For the past six or eight weeks complained of painful sores on the genitals (so called piles), sore throat, also complained of being tired every afternoon and evening.

Physical examination disclosed the remains of an initial lesion of the upper lip, a typical angina with sharp red margins, mucous patches of both tonsils, enlarged, hard posterior submandibular and submaxillary glands. The vulva, perineum, and rectum showed a total of about a dozen large, moist condylomata, varying in size from that of a ten cent to a twenty-five cent silver coin. On June 22, 1912, the day of her first visit, she received a deep hypodermic injection of salicylate of mercury, one grain, also a calomel dusting powder to the moist lesions, and a mouthwash of hydrogen dioxide. June 27, 1912, five days after first treatment, she returned, but although much better generally, no longer feverish, condylomata about one half the original size and perfectly dry. Throat improved. Received injection of salicylate of mercury (1/2 grain), was told to continue the use of the dusting powder and mouthwash. July 2, 1912, condylomata almost gone; mucous patches of throat almost better. Received one and three quarters grains of salicylate of mercury.

of mercury which dose caused the total disappearance of all her active symptoms. She has been under observation and treatment with salicylate of mercury for the past year, during which time there was a gain in weight of about fifteen pounds, so that at the present time she weighs more than at any period of her life. Not only this, but she has had absolutely no symptoms since that time. Of course, mouth treatment, in small or even large doses, could never have caused such a rapid disappearance of lesions. Mercury, the intensive hypodermatic method, is by all means as safe and efficacious as arsenic in any form. The difference between the oral and the hypodermatic administration of mercury, as far as therapeutic efficacy is concerned, is not of much consideration. Mercury can often be given by the mouth to the point of toleration, never by salivation, and yet there be no remission in symptoms, however, upon its hypodermatic administration a prompt improvement takes place.

The following is a history of a clinic case:

Case. Mrs. C. M. came to the clinic complaining of considerable difficulty in swallowing, so much so that she could hardly swallow liquids. The throat was sore. Her speech, with a distinct gagging, examination of the throat, showed a mass of the tonsils, but no abnormality of the uvula. A small pinpoint perforation was found in the center of the mass. The nares were deeply ulcerated. She had already received by mouth a mercuration of eight week's duration, with no improvement of symptoms. On March 4, 1911, she received salicylate of mercury, one grain, by deep hypodermatic injection, also a mercurial mouthwash and gargle. Three days later she returned, feeling and said that within thirty-six hours after the injection she could swallow solid food. March 7, 1911, on examination the perforation was found to be somewhat larger but the mass considerably smaller and less infiltrated. She received this day one and a half grains of salicylate of mercury. March 11, 1911, she returned, and the following note was made: Ulceration of throat markedly improved, slough disappearing; marked improvement of the naso-ulceration. The patient very comfortable as far as the throat was concerned but continuing considerable pain at the site of injection. March 11, 1911, she received two grains of salicylate of mercury by injection.

Up to this date, but not inclusive, the patient had received two and one half grains of salicylate of mercury (that is in a period of eight days), with a remarkable subsidence of symptoms. Cases responding in this manner to hypodermatic medication but not to oral administration are not at all unusual, in fact, they are the rule and not the exception. In a very ignorant, woman, markedly alcoholic, and returned but once more to the clinic. That was on March 14, 1911, which was eleven days after we first started hypodermatic treatment; at this time she was entirely well (symptomatically) with the exception of a small perforation of the soft palate. She objected strenuously to the hypodermics and disappeared from observation.

The following is the report of a case which came to the Post Graduate clinic during March, 1911:

Case. Mr. C. R., aged thirty-nine years, driver.

Marital history: Married fourteen years ago. The first-born showed an erosion involving the buttocks and genitals, also sore eyes and throat. Child was still alive and apparently well. The second conception terminated in an abortion at the third month. The third child was born with a general eruption, sores around the buttocks, etc., and died at the fifth month. The fourth and fifth pregnancies terminated by spontaneous abortions. The sixth and seventh also bore with sores and patches. A severe fever survived, and to this was added the affection of the eyes and poor hearing, also suffers with ulcer of the legs. The first wife died during a succeeding pregnancy supposedly from some heart affection. Patient remarried one year ago. The second wife gave birth to an apparently healthy baby.

Past history: Five months after first marriage, i.e., fourteen years ago began, to complain of headaches and pains in the back (more severe at night). This syndrome continued for about six years, then disappeared spontaneously with no return until fourteen months ago.
Present history: Fourteen months ago he noticed a small abrasion on the under surface of the penis. The wound was treated by a druggist for about six weeks, but spread very rapidly so that at the end of this period an ulceration had appeared. This ulceration was one inch wide and half an inch deep. Present at about this time, patient noticed that during urination the stream of urine instead of appearing at the meatus, was discharged through an opening in the ulcerated area. The ulcerations developed on the throat and the patient became suddenly deaf. He was admitted to a hospital where he received deep intramuscular injections every other day. He received a total of twenty-six injections; also potassium cyanide therapy. He left the hospital partially deaf and remained without symptoms for eight weeks. Then marked ulcerations developed on the head of the penis. He returned to the hospital and again received injections. This time he received one injection a week, for about seven weeks. The lesion healed. Jan. 1, 1911, his throat became so sore that one week after the onset he was unable to swallow solid food because of the severe pain. Each time an attempt was made to swallow, the food regurgitated through the nose. From that time on to the present date, March 16, 1911, the patient has been taking fluids only. During this period patient has been coughing and expectorating every few minutes, and has slept poorly. At times during the night he feels as though he has pneumonia. At one point of his breathing he noted his accessory respiratory muscles. Jan. 1, 1911, weight was 181 pounds. March 16, 1911, weight was 159 pounds.

Physical examination. On March 16, 1911. Throat: The entire surface of the right forearm is swollen. The uvula is swolten to about five times its normal thickness, and about twice its normal length; both tonsils covered with a greenish black slough. Scars of former ulcerations present on the skin of the left side of the nose. On the posterior surface of the right forearm in the upper third there is a squamous lesion about the size of a silver quarter of a dollar, reddish pink in color, circular in outline with a circumference made up of hard infiltrated papules. On the plantar surface of the second toe of the right foot there is a similar lesion. A large circular infiltration is present on the under surface of the penis, about one half inch from the meatus. In the centre of this is a firm, vascular tract leading into the urethra. It is through this artificial urethra that he urinates. No urine appears at the meatus during the act of micturition.

Treatment: The patient received on March 16, 1911, one and three quarter grains of salicylate of mercury by deep hypodermatic injection; also a mouthwash of hydrogen chloride. March 21, 1911, 15 days after the injection he was able to eat solid food, although he had been unable to do so for a period of two and one half months. He had stopped coughing, gagging, and expectorating. He slept every night of the week. He received one and four fifth grains of salicylate of mercury by deep hypodermal injection.

Throat examination showed that the ulcerations of the tonsils had considerably improved. The infiltration of the throat had diminished. The uvula was about one half the size it was five days ago. The patient was a careless individual (alcoholic), and did not return for treatment until two weeks later, on April 5, 1911. Examination on this day showed the throat to be almost normal, except some scarring on the tonsils and the arm and leg were almost healed. He was feeling well in every way, and had gained both in strength and weight. He received one and three quarter grains of salicylate of mercury by injection. The patient has continued to breathe, talk, and swallow normally. The squamous lesions are gone. He weighed 167 pounds, a gain of eight pounds in one month. Conclusions. This patient gave a history of being very careless and negligent in his conduct. He took his medication irregularly. A large percentage of the dispensary patients, continue treatment only as long as symptoms are present. As soon as the active manifestations disappear, they discontinue medication. However, in some patients, particular cases, the disease has progressed beyond the stage to which the intensive treatment. His most marked improvement took place after the first and second injections, so that during a period of five days he received a little over three and one half grains of salicylate of mercury; this dose continued to cause improvement in his symptoms for a period of two weeks following the injection—so that on April 5, 1911, when patient returned, all the throat lesions were gone, and the skin lesions almost so.

In summing up we might say that in the period between March 16, 1911, and April 5, 1911, all symptoms disappeared on a dose of three and one half grains of salicylate of mercury. This is certainly a marvelous result. Of course a patient of this kind who ceases treatment at such a time will sooner or later suffer a relapse. Our object is not alone to obtain a symptomatic improvement or a symptomatic cure, but also a serological one where possible.

The following is the report of a private case referred by Dr. Cyril Barnert:

Case. Mr. F. H., aged thirty-nine years; single, salesman.

Past history: Patient had had several attacks of gonorrhea and one attack of chancre.

Present history: December 19, 1912. This dates back about four weeks, at which time he noticed a hard, painless, nonspreading sore on the penis. The incubation was not exactly known, but between thirteen and twenty-one days (most likely the former).

Physical examination (December 19, 1912) showed a hard, cartilaginous, painless lesion on the frenum about one quarter inch in diameter. The lesion had not been cauterized. Small hard glands were present in the right inguinal region. Scars and papules on the left inguinal and femoral glands. A slight macular eruption was present on the chest. The throat was somewhat congested, but not characteristically so. He was advised to allow scrapings to be taken for spirochete and Wassermann tests. The patient refused, and said he would rather await developments. Received a hydrogen dioxide wash for sore. He returned the following week, December 26, 1912. The chancre and right inguinal glands are harder and larger. There is a typical secondary maculopapular eruption on the chest and abdomen. He has a marked angina, limited characteristically at the upper junction of the pillars of the fauces to the soft palate. Enlarged epicuticular glands present. The patient has complained of occipital and frontal headaches for the past few days. He received sixth tenth grain of salicylate of mercury by deep injection. January 2, 1913. The eruption is still present, but the headache better. Salicylate of mercury one and one half grains by deep injection. January 9, 1913, there is less involvement of the glands, and the papules present on the chest. Not a vestige of the macular eruption remains. Chancre one third its original size; the throat is normal. He has had slight headaches during the week. The patient felt better.

He received one and four fifth grains of salicylate of mercury. He complained considerably of pain in the right buttock and thigh, as a result of the previous injection. January 16, 1913, the papular eruption has gone. Slight remains of the initial lesion still present. He received two and two thirds grains of salicylate of mercury. January 25, 1913, the initial lesion is almost gone. The right epicuticular glands are smaller. The left are gone. The inguinal glands are smaller. He feels better generally, but very he lesion has not disappeared since the onset. He received one and four fifth grains of salicylate of mercury by deep injection. February 1, 1913, the initial lesion is gone. He feels well, but had considerable general reaction has occurred. He received two and two thirds grains of salicylate of mercury. February 13, 1913, he took twelve days' vacation, stopping at a country home. During this period he took plenty of outdoor exercise, sleigh rides, etc., and plenty of nourishment in the form of fresh eggs and milk. He feels considerably better. He is no longer melancholy. He received one and four fifth grains of salicylate of mercury. March 4, 1913, the patient, who is rather alcoholic, commenced to drink heavily, and has failed to appear for treatment. He returned with a relapse of symptoms. During the past few days ulceration has reappeared at the site of his initial lesion, associated with a balanitis. Voice sounds hoarse. The patient received one and one half grains of salicylate of mercury by deep injection, a hydrogen dioxide wash.
for throat, and a calomed dusting powder for the ulcer on the penis. The following week the lesion had gone and the patient was again under control. He has remained symptom free to date but still receiving injections weekly. He has gained in weight and strength.

This case also shows how rapidly secondary symptoms disappear under vigorous mercurial treatment. On February 1, 1913, one month after patient's initial injection, the disease was under control, he having received during that period eight and one half grains of salicylate of mercury. After the second injection the macule were almost gone: only a few papules remained. The total amount of the first and second injections was but two and one tenth grains of salicylate of mercury.

The reason why so many luetic patients do not improve under mercurials, is because of too small doses, improper methods, or a combination of both. This paper is a plea for the more thorough use of intensive doses of mercury by the hypodermatic method.

1007 Forest Avenue.

A NOTE ON THE TREATMENT OF FRACTURES NEAR THE WRIST JOINT WITH ESPECIAL REFERENCE TO COLLES'S FRACTURE.

By A. O. Wilensky, M. D.,
New York,
Attending Surgeon, Mt. Sinai Hospital Dispensary; Adjunct Attending Surgeon, Bronx Hospital and Dispensary.

The literature covering the treatment of fractures at the lower end of the forearm, in close proximity to the wrist joint, and especially, that relating to Colles's fracture, has become so voluminous, that it would seem almost impossible to add anything new. Yet the occurrence, and that very recently, at our dispensary, of several unfortunate results, due to faulty treatment, received at other institutions, seems to indicate that the old fashioned notions of immobilization, have not been entirely eradicated and gives another opportunity for the insistence of early discardance of all splinting apparatus.

I quote the two following cases, numbers 1047 and 1116, series of 1913. Two female patients sustained injuries to their wrists, and the x ray demonstrated the lesions of Colles's fractures. They came to the clinic, with the history, that their forearms had been immobilized, in the one case for seven, and in the other for eight weeks, and when we first saw these patients, their wrist joints were practically ankylosed. Though they were treated for a long time in our mechanotherapeutic department, a very, very indifferent result was obtained. It seems almost impossible, that at this stage of our knowledge, joints would be immobilized for so long a time.

In the treatment of these injuries, we have evolved the following routine. Unless there is marked deformity, we never break up any immation that is present. Most of our cases of Colles's fracture are the mechanical results of a violent jarring of the bone. In a few cases there is practically no deformity, in a large number there is very little deformity. In these cases, the fall on the outstretched hand results in the solution of continuity of the bone within its periosteal sheath. We never break up these fractures, for the reason that whenever we do, we tear the periosteum at the line of fracture, and rip it away from either fragment; and though the immediate result gives us a perfect contour, the final result is disappointing, inasmuch as a fairly large mass of callus always forms, which exaggerates the primary deformity. In a minority of the cases, deformity is very marked, and it is in these cases only, that we attempt its correction. It goes without saying, that here the fracturing force was in excess, and had already torn the periosteum. We immobilize with a plaster of Paris bandage, preferring it for the reasons that it can be very accurately applied; that it takes advantage of all the natural eminences and depressions; and by cutting it through at the sides, it can be converted into a splint that fits the part, and which can be quickly taken off and reapplied.

The important part of the treatment commences now. The cast is converted into a removable splint on the day after it is applied, and every day thereafter, the wrist joint is carefully moved, the muscles of the forearm are methodically massaged, and the motions of the fingers are gone through. In the intervals the splint is worn. On the fifth day, the cast is discarded, and a simple starch bandage is substituted for two days more, after which time all splinting apparatus is discarded. At the end of ten days, power in the muscles of the fractured arm is almost as strong as in the sound limb. At the end of two weeks, these patients are generally back at their work.

Under this line of treatment, these patients have any resultant stiffness: I have never had a case of muscular or ischemic contracture as an unfortunate result. These patients have a minimum of deformity, and perfect function always results. These conclusions are based upon a study of cases under my care at the Mount Sinai Hospital dispensary.

Abstracts and Reviews.

SEVERE ANEMIA IN GASTROINTESTINAL DISEASES.ª

By Professor Adolph Schmidt,
University of Halle, Germany.

The first views regarding pernicious anemia limited the use of this term to those severe anemias which ran a progressively fatal course, and for which no etiological factor, or factors, could be found. This was, perhaps, a sufficient description in the days before the recent development of pathology, but at present it is obviously wholly inadequate. The first steps in advance were made when it was shown that certain cases, clinically in-

ªSummary of a lecture delivered before the Harvey Society, at the Academy of Medicine, October 18, 1913.
distinguishable from the idiopathic pernicious anemia, were associated etiologically with syphilis, pregnancy, septic infections, etc.

With the advance of pathological knowledge there arose two conceptions of the causation of pernicious anemia. The first was that of Ehrlich, who put forward the hypothesis that the condition was primarily a disease of the bone marrow. He called attention to the presence of myelocytes and myeloblasts, along with nucleated red blood cells, and suggested that the underlying cause was a myeloblastic degeneration of the bone marrow. This view was accepted at first, but it was soon found to be quite insufficient, for while many cases did show the presence of myelocytes and myeloblasts in the peripheral circulation, there were many others in which these cells were not to be found, although the clinical picture and course of the disease were in no way different from that encountered in the cases with these abnormal cells.

The discovery and repeated confirmation of the fact that the bothriocephalus was capable of causing a true pernicious anemia, having all of the characteristic signs and symptoms of the idiopathic form and not distinguishable from it in any way, gave a new impetus to the search for the causative factors of the disease. It was soon found that the degenerating portions of the bothriocephalus worm liberated a hemolytic agent in the intestine, which, when absorbed into the blood slowly and continuously, lead to a destruction of the red cells, which in turn was followed by a hyperplasia of the bone marrow, with the throwing off of nucleated red cells, myelocytes, and myeloblasts. Other observers then reported cases of pernicious anemia resulting from other intestinal parasites, including the common Taenia saginata and the ankylostoma, but from neither of these was it possible to isolate a toxin similar to the hemolysin found in the bothriocephalus.

The finding of the bothriocephalus hemolytic toxin indirectly lead Hunter to the formulation of the second theory of causation of pernicious anemia—the hemolytic theory. He was unable to isolate any hemolysin, or even to prove the existence of such a body in the average nonparasitic case of pernicious anemia, but he brought forward a number of facts which seemed to lend support to his view. Among these may be mentioned the characteristic pigmendations of the tissues; the relation between gastric lesions and pernicious anemia—small gastric cancer and achylia gastrica being frequent antecedents of the anemia; and the great accumulation of free iron in the liver, due to the deposition of the iron freed by the hemolysis of the red cells.

Probably Hunter's most valuable contribution was the discovery of the very frequent history in anemic patients of a previous more or less prolonged dyspepsia. Acting upon the suggestions made by Hunter, my assistants and I have been studying the relations between gastrointestinal disorders and pernicious anemia. I have found, excluding those cases which are due to one of the previously mentioned causes, such as parasites, syphilis, sepsis, etc., that pernicious anemia is most frequently encountered in persons who give a definite history of antecedent gastrointestinal dyspepsia.

In my experience the commonest pathological conditions in the gastrointestinal tract, which bear a definite relation to pernicious anemia, are very small gastric cancers, cicatricial tuberculous stenosis (partial) of the small intestine, and the occurrence of achylia gastrica.

It is known that a hemolytic substance can be isolated from the cancerous deposit in the cases of the first group, and it is possible that the absorption of this substance may be the causative factor in the severe anemia encountered in these cases.

In the other two groups—partial cicatricial stenosis, and achylia gastrica—no hemolytic agent has been found heretofore. Hunter suggested that in the latter group there was an alteration in the bacterial flora of the intestine and that some of these bacteria produced a hemolytic substance. Hunter's suggestion breaks down on close examination for: (a). The normal food of man yields an abundance of oleic acid in the intestine which, in turn, yields hemolytic substances through combination with cholesterol and allied materials, these hemolytic substances being found in abundance in normal stools. From this it is almost certain that such hemolytic substances as are liberated in the intestine are not absorbed through the mucosa, hence their presence is of no importance. (b). No constant type of intestinal flora is found in cases of achylia gastrica, and the organisms present do not produce hemolytic bodies. In addition, the liberation of hemolytic toxins from the albuminates in achylia gastrica owing to their incomplete decomposition, does not account for the production of anemia because these substances are not necessarily absorbed.

Nevertheless, in my series of cases of severe and pernicious anemias I have found the previous existence of gastrointestinal dyspepsia to be a very constant feature. Most of these patients give a history of recurrent attacks of slight diarrhea, or of diarrhea alternating with constipation. Their feces are found to be either fairly strongly alkaline or decidedly acid on my test diet. The normal reaction is neutral. An excess of connective tissue fibres and isolated muscle fibres are also present. We have often found, in addition, many degenerated intestinal epithelial cells, or their nuclei. The intestinal muco cosa presents areas of atrophy in the stomach similar to those described by Hunter. Around these there is usually an area of slight chronic inflammation. These facts can not be overlooked, and their importance will be obvious later.

We have sought hemolysins in the blood of these cases of pernicious anemia, but without success until it was shown that in cases in which the blood taken from the peripheral veins contained no hemolysins, blood taken from the portal veins did contain noticeable amounts of these bodies. Their presence in the portal venous system, the hemolysed appearance of the portal blood in these cases, and the excess of free iron in the liver all seemed to confirm the hemolytic view of the origin of the anemia in this group of patients. The question next to be answered was: Where were these hemolysins produced? They were not found in the feces. But they were present in the portal blood,
In a few cases we have been able to answer this question. My assistants have been able to isolate hemolytic substances directly from the intestinal mucosa in several cases in which this tissue presented the characteristic atrophic changes previously mentioned. This suggests that the degenerative processes going on in the intestinal and gastric mucosa of these cases liberate the hemolytic substances which are then constantly entering the circulation in small amounts, and which give rise to the anemia. But these intestinal lesions are not specific, appearing rather as the result of a chronic irritation. This irritation seems due, in turn, to the absence of the normal digestive secretions.

These discoveries would seem to place gastrointestinal dyspepsia in the position of a link between achyia gastrica and pernicious anemia. Even if this is subsequently confirmed we still have a considerable number of cases of pernicious anemia for which we cannot find any etiological factor. I would also call attention to the fact that not only are not all cases of anemia presenting dyspeptic symptoms to be explained thus, but also that many cases fail to show any intestinal lesions such as described, and there is not always a parallelism between the anemia present and the gastrointestinal dyspepsia. The discovery merely adds one more group of causes to those already recognized.

Even after the correction of the dyspepsia the anemia, in many cases, continues to progress. This needs explanation, if the theory is to hold. An explanation is suggested in the discovery that splenectomy has apparently cured some very intractable cases of pernicious anemia. This has given rise to the view that the spleen is capable of storing up a considerable quantity of hemolysins, which continue to act after the cure of the intestinal dyspepsia.

The problem is obviously far from being solved, but we hope that we have added one more cause to those already known.

Certainly our findings lead to several points of value in the treatment of the disease. Inasmuch as gastrointestinal dyspepsia plays a very important part in the etiology of pernicious anemia, this should be treated as early and thoroughly as possible. Proper regulation of the diet is the all important means at our command, and I would offer the following suggestions for the management of these cases:

1. Avoid all irritating substances, such as condiments, wines, etc.
2. The food must be minutely divided, for the stomach cannot break it up in the absence of hydrochloric acid.
3. No raw dishes should be allowed.
4. The diet should be adapted to the individual.
   a. If the feces show signs of fermentation, gas, free starch grains, and are acid in reaction carbohydrates should be reduced or withdrawn entirely.
   b. If they are alkaline, show signs of putrefaction, and contain many free muscle and connective tissue cells proteins, and especially meat should be withheld or reduced.
5. Hydrochloric acid should be used with meals, for by diminishing the gastrointestinal disorder it diminishes the anemia.
6. Lavage of the stomach with physiological salt solution, or with dilute solutions of salicylic acid is very beneficial in reducing putrefactive processes.
7. Lavage of the duodenum is even more beneficial.
8. Intraduodenal insufflation of oxygen has been of considerable value.

While all of these measures have been found beneficial in the treatment of pernicious anemia after it has developed, our recent observations lead to the more valuable applications of these measures to the prophylaxis of the condition through the early rectification of gastrointestinal dyspepsias.

---

**Treatment of Fever in Tuberculosis.**—Thompson Frazer, in the *Therapeutic Gazette* for June, 1913, states that in the presence of a temperature exceeding 101° F., the patient must be put to bed and spared all bodily and mental exertions. With a temperature between 100° and 100.5° F., a compromise may be instituted by allowing the patient to recline on a cot outdoors, while with a fever not over 99.5° F., a comfortable reclining or steamer chair may be used. With the reduction of fever and a persistently normal temperature for several days a moderate amount of exercise is allowed, usually in the form of walking in five or ten minute periods once or twice daily, gradually increased. Sometimes, despite strictly enforced rest in bed, the fever continues, and abates when the patient is allowed somewhat greater freedom, e.g., if the bed is exchanged for the reclining chair, and sitting up and moving about a little are permitted.

In severe cases, with a fever of 103° F. or over, sponge baths often make the patient more comfortable, though the effect on the fever is but temporary. Antipyretic drugs should be used only in cases in which the high fever has seriously impaired the appetite; their continued use is dangerous.

At times, fever may be due to some complication such as a cold, pleurisy, or an ischiorectal abscess, each demanding suitable treatment. Again, it may occur because of gastric or intestinal disorder, in which case calomel and salts will often promptly reduce a sudden, spirited rise that may at first have excited apprehension. A more gradual rise suggests progress of the lung lesion and calls for prompt, absolute rest. Irregular rises due to mental activity or emotional excitement are repeatedly met with; all exciting books and games must be prohibited.

**Treatment of Ozena.—**Sune y Medan, in *Archives internationales de laryngologie, d'otologie et de rhinologie* for March and April, 1913, is credited with the statement that since paraffin injections offer some difficulty in the matter of technique, one should not hesitate to employ other means when the occasion presents. The author himself, after freeing the nasal cavities of crusts, resorts at once to copious insufflations of powdered lactic bacilli. The patient is required to make such insufflations twice daily, having previously irrigated.
the fossæ with boiled saline solution or with a solution made by dissolving into one litre (quart) of boiled water one of the following powders:

R Sodi chloridi, ..........3/ii (60 grammes);
Sodi bicarbonatis, ..........3xxi (85 grammes);
Sodi boratis, ..........3xxii (50 grammes);
Thymolis, ............-gr. xv (1 grammes).
Misce et pone in chartulas No. xvi.

Where the crusts are dry and strongly adherent, the author recommends the use of an ointment containing chloride and bicarbonate of sodium, or one of menthol and resorcinol. The patient returning every week or two, or even oftener, an application of a fluid preparation of lactic bacilli, or an insufflation of a powder, is made.

With this treatment fetor disappears in a few days or, at most, in a week or two; crust formation then diminishes, headache is relieved, the irrigations become unnecessary, and there persists only a slight odorless secretion. Among twenty patients recently treated there have been six cures and fourteen instances of marked improvement.

Treatmnet of Erysipelas.—A. Binet, in Journal de médecine de Paris for April 19, 1913, is credited with the following combination, to be applied to the involved area in erysipelas:

R Tincture iodi, { ..........5x (40 grammes);
Alcoholis, ..........} ..........gr. xlvi (3 grammes).
Misce.

An application should be made at the earliest possible moment, and should extend beyond the erysipelas area, onto the surrounding skin, in order to prevent further spread of the inflammation. Afterward an occlusive dressing should be applied. The iodine mixture should be used once each day, and if a hard layer forms over the epidermis, a little glycerin should be employed as a deterrent. The effect of the iodine is to rapidly remove the edematous, shining appearance of the involved skin and cause it to shrink and sometimes to become finely fissured. After the fifth or sixth application desquamation takes place, and it is then time to discontinue the iodine applications. Generally at this period the patient's temperature falls and the general condition shows improvement.

Treatment of Mushroom Poisoning.—A. Pic and J. F. Martin, in Lyon médical for June 15, 1913, report a case of severe poisoning by Amanita phalloides in which the production of a fixation abscess appeared responsible for the patient's recovery. The symptoms, as is usual in poisoning by this species of fungus, came on only a number of hours after its ingestion, and the mushrooms had therefore already passed from the stomach into the intestine, rendering emesis practically useless. For four days after the admission of the patient to a hospital, injections of 10 ounces (300 grammes) of normal saline solution were given twice daily to wash the blood. Sedative hot enemas were also given, and the patient bathed in water at body temperature for ten minutes three times daily. The heart action was stimulated with injections of camphorated oil. To the fixation abscess, however, more than to any other measure, seemed due a sudden improvement in the patient's condition, which took place on the ninth day. This was the day on which fluctuation was first noted in the abscess. Diuresis set in, and the pain and all other symptoms were relieved, soon after to disappear entirely. The authors argue that, just as in infections the causative microorganisms, and in lead or mercurial poisoning the respective metals, are found in the pus of a fixation abscess, so in Amanita phalloides poisoning the phallin becomes fixed in the abscess. In previous experience with this method of treatment in a series of cases, the authors had observed that whereas, among thirty-eight previously reported cases of phallin poisoning the mortality had been 86.8 per cent, that among twenty-three patients suffering from the same variety of poisoning, and treated with fixation abscesses, the mortality had been only 39 per cent.

Treatment of Cardiac Disturbances in Chronic Dyspepsia.—R. Oppenheim, in Progrès médical for March 15, 1913, discussing the treatment of complaints such as palpitation, intermitteances, tachycardia, bradycardia, pseudoanginal attacks, etc., advises, in the first place, strict dieting according to the form of digestive disturbance present, the reduction of starchy foods to a minimum, and the taking of a light evening meal. Constipation must be prevented. If necessary, a teaspoonful of the following preparation may be taken in a little water at bedtime:

R Fluidextracti franguli...{ ..........5vi (25 grammes);
Fluidextracti rhamni..........; purshiane, ..........}
Glycerini, ..........5x (40 grammes).
Misce.

A cool moist compress, covered with some impervious material, may be left upon the epigastric and precordial regions overnight; or, a compress moistened with alcohol may be applied morning and evening for half an hour. One of the following pills should be taken at night:

R Extracti hyoscyami, ..........5i (0.05 grammes).
Fluidextracti valerianae, ..........5i (30 grammes).
Zinci oxidii, .......... 
Fit pilula No. i.

When cardiac discomfort appears, the following ointment, recommended by Robin, should be lightly rubbed over the precordium:

R Veratrina, ..........gr. iiss (0.15 grammes);
Extracti opii, ..........-gr. xii (0.75 grammes);
Olei terebinthinae rectificati, ..........5ss (2 grammes);
Olei menthe piperitae, ..........; gt. xii;
Adipis lane hydrosi, ..........5i (30 grammes).
Misce. Fiat unguentum.

The patient should then take every hour, until the attack ceases, a tablespoonful of a sedative preparation:

R Potassium bromide, ..........5i (6 grammes);
Cherry-laurel water, ..........5i (30 grammes);
Syrup of ether, ..........5i (110 grammes).
Valerian distillate, ..........5i (30 grammes);
Mix and make into a solution.

The syrup of ether contains two per cent. of ether and five per cent. of alcohol; the valerian distillate is made by macerating one part of valerian with eight parts of water for twelve hours, distilling, evaporating to four parts, and filtering.

THE THYROID GLAND AND CHRONIC RHEUMATISM.

Considerable evidence has accumulated to the effect that at least a small proportion of cases of chronic rheumatism may be due to deficient functional activity of the thyroid. Among the facts which have pointed to such a connection may be mentioned the many cases in which thyroid gland has proved very beneficial and sometimes curative: the concomitance of myxedema and chronic rheumatism; thyroid treatment benefiting both conditions: the appearance of chronic rheumatism and myxedema as a result of X ray treatment applied to the neck for trichosis in such a way as accidentally to produce thyroid atrophy, both disorders being markedly benefited by the remedial use of thyroid glands: the concurrence of chronic rheumatism with fibrous degeneration of the thyroid: the disappearance of rheumatism due to hypothyroidism, on the appearance in the same patient of Graves's disease, etc. While this class of evidence has been suggestive, it has always lacked the confirmation which the presence of histological lesions in the thyroid alone in a marked case of chronic rheumatism would furnish. Such a case has, however, been reported recently by Aubertin and Pascano (Presse médicale, September 27, 1913). The patient, a woman of forty-eight years, had suffered from chronic articular rheumatism since the age of twenty years to such a degree, and with periodical exacerbations so severe, that all the joints had become deformed, sufficiently so indeed to cause marked distortion of the limbs, the patient being unable to ambulate at all without crutches. Sudden death having been caused by an embolus, a careful examination of all the organs revealed pathological lesions, other than the resulting cardiac changes, in but one, the thyroid. These lesions were very intense and of long standing, recalling those of congenital myxedema, cicatricial fibrous tissue with chocking of the vessels and cysts predominating. The morbid changes in the heart were those commonly observed in chronic rheumatism as a sequel to that disease—a part in other words of the morbid process. In five other cases of chronic rheumatism the authors also found, at autopsy, lesions of the thyroid in four instances, the only case in which the organic changes, sclerosis, etc., were not marked, having shown a relatively benign course and much less deformity. These, however, were not as clearly ascribable to the thyroid as in the case first described, the patients being aged or tuberculous, both of which conditions might have entailed the organic changes observed in the glands. The first case clearly indicated, however, that the thyroid gland must be considered as a factor in the pathogenesis of a certain proportion of cases of chronic rheumatism, particularly in those attended with deformity.

Irrespective of these severe cases, there is a form of rheumatism not infrequently met with which is distinctly due to hypothyroidia and associated with the characteristic symptoms of this condition: it consists of severe pain in the occipital region or between the shoulderblades, which rest in bed tends to aggravate rather than improve. Such cases never yield to the salicylates and other agents used commonly in the various forms of rheumatism: but the patients gradually recover under the persistent use of desiccated thyroid gland. Care must be taken, however, to avoid large doses. The so-called “average dose” of the United States pharmacopoeia is positively dangerous here: in no case should the initial dose of desiccated gland exceed one gram.

ALCOHOL AS A THERAPEUTIC AGENT.

The exact pharmacological classification of alcohol, so long and so universally regarded as a typical stimulant, is no doubt at the present time considered by most to be a matter sub judice. It is a well known fact, however, that during the last few years there has been accumulating a mass of experimen-
EDITORIAL ARTICLES.

827

tal testimony, from skilled investigators, which indicates that it is a narcotic, rather than a stimulant, and some extremists, holding that it is an anesthetic and depressing toxin, which in disease destroys the normal activities of the nerve cells and centres, would banish its use from medicine altogether. It is also a fact that in recent years its employment as a therapeutic agent has become very considerably restricted, as compared with former usage. But, on the other hand, it is unquestionably the case that among clinicians generally alcohol is still held in the highest esteem in certain conditions, in some of which no other agent appears to be equally efficient. Thus, at one of the recent meetings of the American Therapeutic Society, when Doctor Crothers read a paper in which he characterized the use of alcohol in medicine as a “delusion founded on misconception and false reasoning, with the accumulated prejudices of ages,” Doctor Alexander Blackader, professor of therapeutics in McGill University, in discussing it, said he would like to place himself on record as “belonging to the old school who still think they see benefit not infrequently arising from the use of alcohol as a prompt, although fleeting, stimulant. In prolonged pyrexia it conserves nutrition and is utilized as a food. The time has not yet come when we can altogether dispense with alcohol in our pharmacopeias.” Whatever the results of laboratory investigations may be, certainly the weight of clinical experience cannot be disregarded.

In American Medicine, for September, Doctor A. Jacobi states that no amount of whiskey will lead to intoxication when its effect is needed to combat sepsis, and that his cases of thorough sepsis relieved or cured by alcohol extend over more than half a century. Among these were cases of diphtheria with mixed infection, where his experience had shown that no such infection was amenable to the action of antitoxine. The late Austin Flint, than whom we have never had a physician of more extended clinical experience or keenest observation, was throughout his long career a strong advocate of the judicious use of alcohol. He never advised it unless there were present what he believed to be distinct indications for its employment, but in cases where such were present he did not hesitate to prescribe it in enormous quantities. In his Practice he records instances in which desperate, and even apparently hopeless, cases were undoubtedly saved, like some of those cited by Doctor Jacobi, by this course.

There would seem to be little doubt, in the light of the later investigations, that alcohol may act as a narcotic; but the acceptance of this theory is by no means equivalent to condemning its therapeutic use for its effects on the brain. On the contrary, Cushny maintains that this depressant action, far from being in conflict with its clinical employment, supplies a definite and logical explanation of the improvement noted in a large number of instances where the effect of alcohol in allaying the subjective symptoms, relieving the nervous strain, and promoting the rest and comfort of the patient is not surpassed by that of any other drug. Accordingly, he says, it would seem a question whether the results aimed at by the clinician when he prescribes alcohol have not been misnamed “stimulation” (the word being used in quite a different sense from that in which it is understood by the experimental observer), and are not in reality narcotic in their nature, and hence in entire agreement with the experimental results.

THOROUGHNESS IN MOSQUITO EXTERMINATION.

Many a community has failed in its efforts for mosquito extermination and has given up in disgust; the reason for which has been almost invariably that somewhere, some breeding place, has been ignored as too trifling for consideration. A single negligent householder may nullify the zeal of a whole neighborhood. The only means whereby mosquitoes can be permanently vanquished is to destroy their breeding places, which may be anywhere that water can accumulate and stand quiescent for ten days or more. Breeding only occurs in stagnant water. It is excellent to drain marshes, pools, springs, ponds, fountains, wet places, lawns, and gardens, but extermination will not be thorough and effective unless one realizes that no body of water, not even a teaspoonful, can be too small for the breeding place of a mosquito, especially if grass and algae abound in and about it. Myriads may breed in a water puddle by the roadside; in water troughs infrequently used; in chicken pans; in poultry yards; in water cups standing on the frames of grindstones; in accumulations of water in garden furrows, or in fields; on moist, mossy, and especially clayey soils; on any tree, in crotches, hollow, or pocket; in footprints of animals in marshy lands or along the road; in irrigation ditches and excavations; in drains and gutters choked with grass or weeds; on defective roofs and in eave gutters; in old boats along the water fronts; in the hollows of rocks; in the beds of old canals; wherever there is green scum in the backwaters even of rapid streams; in pools by the side of open streams; in earthenware vessels; in water barrels and in tubs; in cesspools or disused wells; in beer or soda water bottles, broken or otherwise; in the water tank of an acetylene gas machine; on fragments of broken
EDITORIAL ARTICLES.

RExlex Contractiona of the Large Intestine and Reflexotherapy.

H. Lebon and P. Aubourg, in the Presse médicale of August 23, 1913, stated that they had ascertained, upon administering castor oil, then a bismuth suspension, and finally examining the subject with the x rays, that electrical stimulation of the right pneumogastric nerve in the neck caused contractions of the ascending colon, sufficiently marked to be plainly visible on the screen at each excitation of the nerve. Similar stimulation of the crural or sciatic nerves produced little or no change in the colon. Upon applying one electrode to the right pneumogastric and introducing the other into the stomach as a sound, spasm of the ascending colon occurred. Vigorous percussion of the seventh cervical spinous process was found to cause the eecum to rise and the ascending colon to become broader; such effects were observed in all persons examined except one—a woman with marked enterospasm and constipation. Percussion of the dorsal spines had no effect on the colon until the lowest ones were reached: percussion of these, or of the lumbar spines, brought the physicians in charge have considered this matter very carefully. The Journal has published several original articles dealing with this subject. In one of these the point was well brought out that the Binet-Simon test, for example, is well adapted for certain localities in France, say Paris, while it would be wrong to adapt it to a certain locality in Italy, say one of the poorer districts of Sicily. Along these lines, a similar test has been exploited for American school children. But to adopt this or similar tests for the immigrant would be unfair. Let us take for example an illiterate Polish farm hand, forty years of age, who never served in the army, who never left his village, but through industry, his knowledge as a farm hand, and by stinting himself of everything that was not absolutely necessary to life, was able to save enough money to emigrate to the land of hopes and have a small balance to start life over again. To ask such a man to repeat four, five, six, or seven digits is an absolutely unjust test, for never in his life had he had to do with numbers consisting of more than two or three figures, and still we are sure he would be a very desirable citizen. This man should be asked questions which deal with his daily life routine, questions which would be easy for him to answer would be difficult for his examiner, who, being city bred, would be unfamiliar with anything about farm life. We believe that the examination of mental ability should be adapted to the previous environments and trade of the adult immigrant, and not based upon theoretical pedagogic questions which could readily be answered by the average school boy, but seldom or not at all by a professor of Sanskrit.

EXAMINATION OF FEEBLEMINDED IMMIGRANTS.

The examination of feebleminded immigrants is a question of vital interest to the medical officers at our ports of entry. Many systems have been developed to carry out these investigations. and naturally
about contractions of the colon in all its divisions. The authors believe that percussion of the lowest dorsal and lumbar spines, or vibratory massage of this region, may be of service in the treatment of constipation, whether due to muscular weakness, insufficiency of intestinal reflexes, inhibition of the bowel contractions, or enterospasm.

**SELF INFlicted Eruptions.**

Harvey P. Towle, in an editorial in *The Journal of Cutaneous Diseases*, September, 1913, dwells upon the unsettled state of dermatological opinion in regard to the cause of ulcerative eruptions in hysteria. Etiologically the cases may be divided into two groups. In the first group may be placed those ulcerative lesions of hysteria, based on the proved fact of self infliction. The second group contains all other cases, but the etiological theories are so numerous and discordant and split this group into so many small divisions that its right to a separate classification is very doubtful. Clinically the cases of the first and second groups do not differ, but from an etiological viewpoint they differ. The cases of the first and second group both occur in hysteria. The author feels that when one regards hysteria more as a psychic disease than a physical ailment, that the causative factor of these hysterical ulcerative skin lesions will become more evident.

**News Items.**

**Philadelphia County Medical Society.**—A special meeting of this society will be held in the College of Physicians building, on Wednesday evening, November 12th, to take action on the question of amending the charter of the society.

**Plague in Russia.**—According to press dispatches plague has broken out in a suburb of Novo-Tcherkask, capital of the territory of the Don Cossacks. Eleven deaths have occurred, and the town is placed under military quarantine.

**Professor Shadrer Finds Another Radium Spring.**—It is reported that Professor J. H. Shadrer, of Williams College, has discovered another deposit of radium near Williamstown, Mass., has found another spring of the same kind. The practicability of driving shafts and mining the radium is under consideration.

**Medical Society of Hudson County, N. J.**—Dr. E. T. Steadman, of Hoboken, was elected president of the society, at its annual meeting held recently in Jersey City, to succeed Dr. Wallace B. Pyle, of Jersey City. Other officers elected were: Dr. Henry J. Bogardus, vice-president; Dr. Charles H. Finke, secretary; Dr. Henry H. Brinkerhoff, treasurer, and Dr. William Friele, reporter.

**Harvey Society Lectures.**—Dr. Charles V. Chapin, of the Health Department of Providence, R. I., will deliver the third lecture in the series on the evening of Saturday, November 1st, his subject being the Air as a Vehicle of Infection. The fourth lecture will be given on Saturday, November 29th, by Professor G. H. Parker, of Harvard University, on the Nervous System; Its Origin and Evolution.

**A Whooping Cough Camp.**—The trustees of St. John’s Guild have decided to start a whooping cough camp on the floating hospital Helen C. Jailliard. It will be operated in cooperation with the Department of Health, and will be in charge of Dr. John L. Baker, who has established several dispensaries and camps for the treatment of this disease. The plan will not interfere with the summer work of the floating hospital, as the boat will be used as a whooping cough camp only in the winter season. A feature of the work will be the instruction of mothers in the care of their children at home.

**Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.**—Monday, October 27th, Section in General Medicine of the College of Physicians, and the North Branch of the Philadelphia County Medical Society; Thursday, October 30th, Medical Legal Society and the West Philadelphia Medical Association; Thursday, October 30th, Germantown Branch of the Philadelphia County Medical Society.

**An Epidemic of Scarlet Fever in Maryland.**—It is reported that an epidemic of scarlet fever exists in Cecil County, Maryland. The disease is scattered over a large territory, and it is said that the situation is somewhat alarming. Dr. Fulton S. Cutten, president of the State Board of Health, has taken charge of the matter, and the necessary measures are being taken to control the epidemic. All schools and churches in the affected districts have been closed, and the most rigid quarantine is being enforced.

**Medical Society of the County of Wyoming, N. Y.**—The following officers were elected at the annual meeting of this society, held in Warsaw on Tuesday afternoon, October 14th: President, Dr. W. J. French, of Pike; vice-president, Dr. W. R. Thompson, of Warsaw, reelected; secretary and treasurer, Dr. L. H. Humphrey, of Silver Springs. The next meeting of the society will be held in Castle in January. The principal features of the programme were papers by Dr. Roswell Park and Dr. E. B. Strader, of Buffalo.

**Obstetrical and Gynecological Society of Washington, D. C.**—At the annual meeting of this society, held on Friday, October 10th, the following officers were elected: President, Dr. J. F. Moran; vice-presidents, Dr. G. J. Miller and Dr. S. Prentiss; treasurer, Dr. J. R. Porter; secretary, Dr. W. W. Miles; and Dr. Truman Abbe; assistant treasurer, Dr. D. W. Prentiss; business committee, Dr. G. Tully Vaughan, Dr. A. R. Shands, and Dr. Truman Abbe; admissions committee, Dr. Thomas F. Lowe, Dr. H. W. Lawson, and Dr. Karl Corley; publication committee, Dr. Truman Abbe, Dr. W. W. Miles, and Dr. E. A. Balloch.

**Medical Society of the County of Madison, N. Y.**—This society met in annual session on Tuesday afternoon, October 14th, in Oneida, N. Y., and elected the following officers to serve for the ensuing year: President, Dr. William T. Tanner, of Oneida; vice-president, Dr. A. K. Thomas, of West Eaton; treasurer, Dr. C. H. Perry, of Oneida; secretary, Dr. George W. Miles, of Oneida; censors, Dr. William Taylor, of Canastota, and Dr. C. H. Perry. Dr. George W. Miles was chosen delegate to the annual meeting of the State society. The semiannual meeting of the association will be held in Canastota in May.

**Ether Day at the Massachusetts General Hospital.**—Dr. Milton J. Rosenau, professor of preventive medicine in the Harvard Medical School, was the principal speaker at the Ether Day exercises at the Massachusetts General Hospital, Boston, on Thursday, October 16th, his subject being the prevention of disease. At the banquet which was held at the close of the exercises, addresses were made by President Lowell, of Harvard University; Dr. Richard C. Cabot, Dr. F. A. Washburn, Jr., and Dr. John G. Blake, Dr. Abner Post was elected president of the alumni; Dr. F. B. Harrington, Dr. Francis S. Watson, and Dr. S. J. Mixter, were elected vice-presidents, and Dr. C. B. Hollings, secretary-treasurer.

**Personal.**—Dr. Carl Voeglin, associate professor of pharmacology at Johns Hopkins University, has been appointed professor of pharmacology in the Hygienic Laboratory of the United States Public Health Service, Washington, D. C., to succeed Professor Reid, who has recently resigned to become head of the department of pharmacology at Harvard University.

Dr. Christian R. Holmes has been elected dean of the medical college of the University of the Philippines, on the unanimous vote of the board of trustees of the institution. Doctor Holmes succeeds Dr. Paul G. Woolley, who resigned last spring.

Dr. Downey L. Harris has tendered his resignation as director of the St. Louis City Laboratory of Pathology and Bacteriology to accept the chair of hygiene and preventive medicine in the St. Louis University Medical School. His resignation becomes effective on November 1st.

Dr. Joseph Moore, of the Manhattan State Hospital, Ward’s Island, has been appointed first assistant physician at the Matteawan State Hospital.
The Thubert Medical Society.—The sixtieth anniversary of the organization of this society was celebrated at the annual meeting held in Milford, Mass., on Thursday, October 9th. Dr. Charles H. Randall, of Woonsocket, R. I., delivered the annual oration, his subject being "Science and Tomorrow." Dr. William L. Johnson, of Uxbridge, acted as toastmaster at the banquet and among those who responded to toasts were Dr. W. P. Bowers, of Clinton, Mass., Dr. Homer Gage, of Wrentham, Dr. Alfred Worcester, of Waldham, and Dr. John M. Huntington, of Rutland. The business meeting which preceded the oration and the banquet the following officers were elected: Dr. John V. Gallagher, of Milford, president; Dr. George L. Wallace, of Wrentham, vice-president; Dr. A. J. Galligan, of Franklin, secretary; Dr. J. W. Ledbury, of Uxbridge, treasurer; Dr. C. M. French, of Milford, librarian; Dr. J. M. Gallison, of Boston, orator for 1914; Dr. George L. Wallace, alternate.

Woman Scientist to Engage in Research Work in Radioactivity at Yale University.—Miss Ellen Gleditsch, for five years a collaborator and associate of Mme. Curie in Paris while Mme. Curie was investigating radioactivity, has come to this country for the purpose of conducting experiments in radioactivity at Yale University. Miss Gleditsch is a Norwegian investigator in physical chemistry and was designated by the Government Commission of Norway as one of the six scientists sent to the United States for advanced research work in American universities under the auspices of the American Scandinavian Foundation, which foundation consists of a self-perpetuating body, incorporated in 1911, to hold in trust an endowment of $600,000 created by the late Miss Niels Nelson, of Brooklyn. Its purpose is to cultivate closer intellectual relations between the United States and the Scandinavian countries. It carries with it six fellowships, the holders of which are designated by Government Commissions in Norway and Sweden, and Miss Gleditsch is the first woman ever to receive an appointment to one of these fellowships.

Vermont State Medical Society.—The one hundredth annual meeting of this society, which was held in Burlington, Vermont, Wednesday, Thursday, and Friday, October 8th, 9th, and 10th, was one of the most successful ever held by the organization. The registration was nearly double that of other years, and the programme more elaborate. The proceedings were brought to a close by a banquet, nearly one hundred guests being present. Dr. Walter L. Havens, of Chester, acted as toastmaster, and among those who responded to toasts were Dr. Alexander R. Craig, of Chicago; Dr. C. S. Caverly, of Rutland; Dr. W. Gilman Thompson, of New York; Doctor Marcy, of Montreal; Dr. C. R. Rockwell, of Washington; Dr. C. V. Draper, of Rutland; Dr. W. N. Bryant, of Ludlow. Officers for the ensuing year were elected as follows: President, Dr. A. L. Miner, of Bellows Falls; vice-president, Dr. Grace Sherwood, of St. Albans; secretary, Dr. J. M. Hamilton, of Rutland; treasurer, Dr. Charles F. Dutton, of Burlington; auditor, Dr. C. F. Ball, of Rutland, and annuity chairman, Dr. C. A. Cramton, of St. Johnsbury. Dr. C. H. Beecher, who had been the secretary of the society for six years, declined to accept the office again, and was elected delegate to the annual meeting of the American Medical Association.

Delaware State Medical Society.—At the annual meeting of this association, held last week in Dover, the following officers were elected to serve for the ensuing year: President, Dr. William P. Orr, of Lewes; vice-presidents, Dr. T. P. Davis, of Newcastle, and Dr. William Marshall, of Milford; secretary, Dr. G. W. K. Forrest, of Wilmington; treasurer, Dr. S. C. Rumford, of Wilmington; councillor, Dr. J. H. Wilson, of Dover; delegate to the American Medical Association, Dr. H. W. Briggs, of Wilmington; trustee of the medical journal, Dr. George W. Marshall, of Milford; examiner to the state board of examiners, Dr. H. W. Briggs; Dr. John Ball, Dr. George W. Marshall, Dr. Rowland C. Paynter, Dr. Robert Eliegood, Dr. W. H. Kraemer, Dr. P. S. Downes, Dr. E. S. Duvall, James Beebe, and Dr. J. W. Blasman; examiners, committee on scientific work, the committee on printing, and the committee on medical education; public policy and legislation, Dr. P. W. Tomlinson, Dr. G. W. Marshall, and Dr. J. H. Hammond; medical education, Dr. E. S. Dwight; necrology, Dr. J. P. Lolland, Dr. Walter Ellis, and Dr. W. T. Jones.

The Pith of Progressive Literature.

DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT.

September 4, 1913.

Additional Contribution to the Question of Rickets; Phosphorous and Codliver Oil.—Max Kassowitz states that the calcium balance experiments cannot clear up the processes taking place in the bony skeleton, since even in the healthy child the calcium varies greatly, due in all probability to changes in the intestinal tract. For therapeutic purposes in rickets phosphorus is the ideal remedy, and it is immaterial in what form it is administered. Codliver oil is, from a practical standpoint, beneficial.

The Treatment of Cancer with Mesothorium and its Combination with Other Methods of Treatment.—A. Pinkuss says that the local action of the Röntgen rays, radium, or mesothorium upon cancer can destroy it to a certain depth, but one must guard against the idea that the sole treatment with the rays furnishes a sure method for the removal of cancer. The difficulty of making mesothorium and the expense of it when obtained prohibits its general use; the techne of its application is by no means fully developed and, furthermore, it is doubtful whether the mesothorium emansiations can prevent the development of metastases even though the rays seem to have cured the original lesion. The combining of the emansiations with the injection of thorium X and solutions of the same substance with the internal administration of pancreatins, etc., can give positive cures. The old rule still holds good, however, namely, that every operable carcinoma whose risks of removal are not too great should be operated on because removal by operation at the present time is still the safest and surest way of exterminating malignant tumors.

Metamorphoses of Primary Skin Efflorescences.—K. Herxheimer noticed in a great number of cases how primary blebs and pustules in syphilis, Dühring's disease, herpes genitalis, labialis, and perianalis, varicella, eczema, urticaria recidiva (strophulus infantum), and simple pyoderma underwent change into lichenoid papules; evidently an expression on the part of the organism to transmute an acute inflammation, which would not subside rapidly into a more chronic process.

The Value of the Cyanide of Gold and Potassium in the Treatment of Lupus Vulgaris and Erythematodes.—The results obtained from the use of the cyanide of gold and potassium combined with tuberculosis in the treatment of lupus are not entirely satisfactory, but admit of improvement. On the other hand good scar tissue was obtained with gold, tuberculin, and pyrogallus.

Increased Mortality of Infants in Spring.—H. Liebfmann observes that the increased mortality during the warm days of spring is not due so much to the spoiled milk as to the direct injury of the infants by the heat, boys being more susceptible to it than girls.

Advantages of Pituglandol in Obstetrical Practice of the General Practitioner.—H. Bosses recommends the injection of pituglandol (Roche).
one c.c. of the ten per cent. extract. It is an excellent oxytoxic for the stage of expulsion. Its prophylactic injection is particularly to be recommended in all operative procedures terminating labor to prevent atony of the uterus.

Noviform.—O. Fresse finds that in rhinology and laryngology noviform in powder or on gauze is used with satisfaction for postoperative treatment or for inflammatory or ulcerative processes. Its action is antiseptic and astringent; its deodorizing property is not sufficiently strong to overcome the fetor in pronounced ozena.

Embarin.—M. Salomonski remarks that the rise in popularity of which mercury is beginning to enjoy when its results are compared with those of salvarsan brings the other mercurial preparations into prominence again. Embarin is a mercurial preparation, soluble in water, and is injected daily for about twenty days. That the results are good are demonstrated by the fact that the Wassermann reaction becomes negative. Secondary action on the kidneys is not to be feared. Some patients react vigorously and with alarming symptoms after the injection, and since toleration is not produced its discontinuance in such cases is to be advised.

Aberdhalen’s Dialysis in Tuberculosis of the Lungs.—A. E. Lampé found that the serum of those mildly tuberculous, and also of some patients who did not appear to be tuberculous clinically, reduced as a rule only the proted of the tubercle bacilli; the serum of advanced tuberculous patients reduced only lung tissue both tuberculous and normal. These findings are explained by supposing that in the early stage of the disease the protodermferment of the organism at first acted on the proted of the tubercle bacilli in the blood.

Nature of the Thymus Gland According to Experiments on the Possibility of Regeneration in Mammals.—Francesco Fulei avers that while marked individual differences occur in the thymus no influence seems to be exerted by sex or age, in animals under examination, namely, rabbits, dogs, cats, rats, chickens, etc. The thymus possesses a decided capability of regeneration after partial extirpation. The histology shows four stages, epithelial stage, stage of the “reversed thymus,” lymphoid stage, and, lastly, the stage of the normally formed thymus. The stimulative effects produced by the extirpation of the sexual organs on the regeneration could not be proved. The thymus is an epithelial organ with a richly vascular connective tissue stroma.

The Relation of Experimentally Produced Syphilis of Animals to Lues in Man.—A. Busche reports that a man who had always enjoyed good health was accidentally pricked by a needle used on the testicle of a syphilitic rabbit and acquired pronounced syphilis. It is thus for the first time proved that syphilis of the rabbit is identical with syphilis in man. The virus does not become attenuated for man by repeated passage through animals. Therefore Metchnikoff’s expectation of producing antiluetic vaccine for man by passage through animals is groundless.

Internal Treatment of Basedow’s Disease.—W. H. Becker insists upon the necessity of the internist presenting the statistics of a large number of cases with Basedow’s disease. His report of sixty-one cases treated internally since the year 1890 cannot be placed against the vast material gathered by the surgeons. Since there are certain objections to the operative treatment the author takes the standpoint of the golden mean.

Experiments and Therapeutic Experiences with Diathermy.—H. Dressen asserts that comparative investigations with pulsities stangero-themy, thermography, and diathermy have shown the superiority of the latter, only by its means is it possible in a short space of time to produce in the inner parts of the body a high grade of heat without effects upon the skin. The details of the technic must of course be well known. How far the therapeutic efficacy of diathermy will go it is for future detailed experiments to determine.

Pathogenesis and Therapy of Paroxysmal Tachycardia.—R. Kaufmann and H. Popper describe a case which showed clinically attacks of paroxysmal tachycardia with changing arrhythmia and where the cardiosphygmograph revealed that the attacks commenced at Tawara’s nodes and that the arrhythmia was condition by a change in the starting points of the heart’s contractions and also by varying degrees of sinoauricular block. The attacks disappeared upon the administration of large doses of physostigmine combined with strophanthus. The heart’s mechanism then changed to arrhythmia perpetua. The administration of atropine produced in time pulse which was regular and of normal frequency.

Clinical and Experimental Investigations of Hypophyse.—J. Seng finds that hypophyse is a good remedy for overcoming primary and secondary inertia and for controlling hemorrhage after birth. Induction of labor at term cannot be produced by hypophyse; nor is it possible to induce abortion by its aid.

The Present Status of Organic Transplantation.—R. Stich says that to-day the homotransplantation of the larger organs by means of arterial suture is as practicable as heterotransplantation. In his critical bird’s eye view of this whole subject as at present successfully practised on animals, he of course refers to the work of Carrel and others. The kidneys, adrenals, thyroid, parathyroids, ovaries, spleen, heart, lungs, intestines, and other parts of the body come in for their share of discussion. Before success is possible the biological difference between the recipient and the donor will have to be reduced to zero. This to-day is impossible with animals of different species. Even in animals of the same species the results are in their infancy.

Treatment of Acute Bronchitis, Bronchilitis, and Bronchopneumonia in Infants and Young Children, Particularly with Hot Baths.—Arnth reviews the subject of hydrotherapy in these conditions. For some time past he has placed these patients in hot baths. The water is raised to 41° C., the child being immersed every three hours up to five baths daily. The arrangements in the clinic for facilitating this work are of the simplest. When
the temperature of the child does not exceed 39° C. The bath is given for ten minutes, three times daily. The water is kept at an even temperature by the addition of more hot water. The rationale of this treatment consists in the fact that the peripheral bloodvessels are dilated by heat and this draws the internal heat of the body to the surface. The author found in many carefully taken records that the rectal temperature of 41° C. decreased a few degrees after the bath, the greatest fall occurring from one to one half hour after the bath. Therefore the theory of congestion of the internal organs by hot baths is not supported by these findings. The author is not prepared to state whether the hot bath exerts an inhibitory influence upon the central heat mechanism. Bronchitis and bronchopneumonia in infants and young children are especially benefited by the application of these hot baths. They are specific in these cases. They reduce the fever, stimulate expecoration, deepen the respirations, thus preventing atelectasis, have a sedative and soporific effect and directly stimulate the excretory glands of the skin. Since these hot baths have been in use uniform recovery has been the rule from these conditions. The course of the disease is also markedly shortened. Many charts in this article give the details of this treatment.

**New Addition from the Realm of the Diagnostic Examination of the Blood and Cerebrospinal Fluid in Diseases of the Central Nervous System.**—Victor Kafka recommends considering the whole blood picture in making diagnostic use of the blood and fluid reactions which yield characteristic findings. The presence of fibrinoglobulin, found by saturating the liquor by the addition of twenty-eight per cent, of ammonium sulphate, is of particular significance in many cases. Fibrinogen and fibrinoglobulin are only found in certain pathological conditions, while fibrin was present in all cases examined.

**MÜNCHENER MEDIZINISCHE WOCHENSCHRIFT.**

*September 20, 1913.*

**Experimental Hyperglycemia by Intravenous Injection of Sugar.**—S. J. Thannhauser and Helene Pfitzer found that in all patients the injection of grape sugar was borne without discomfort. Only in two was there a slight temperature elevation. Twenty grains of grape sugar were injected. One quarter of an hour after the injection, one grain of sugar was recovered from the urine. The excretion of sugar did not increase in proportion to the amount injected. By injecting 300 c. c. of seven per cent. grape sugar, the sugar content of the blood is normal after a quarter of an hour. In hepatic diseases the hyperglycemia continues for hours after the injection without any evidence of glycosuria. In chronic nephritis there is an acute rise, and a decrease within a quarter of an hour to only a slight glycosuria. In severe diabetes mellitus the entire injection of grape sugar is excreted. In light cases one or two moderate portions are excreted in the urine. In severe cases the sugar curve charted was not steep, but long and flat. In light cases it resembles the normal.

**Diastase Content of Feces.**—H. Rotky explains the technic of his experiments as follows: For estimating the diastase in feces by quantitative comparisons, the author uses the Wohlgemuth method. Graduated quantities of the ferment solution are placed in reagent glasses, adding one per cent. of soluble starch solution, and kept at an even temperature for a definite time. After the digestion is complete the tubes are filled with water and one drop of \[ \frac{n}{10} \] iodine solution is added. From the appearance of a blue line, the presence of undigested starch is recognized. The amount of ferment in the tubes serves to gauge the diastatic strength. This method used for testing saliva and blood serum by Wohlgemuth is also used for feces. The author finds that in the feces the activity of diastase depends upon the concentration of salt. To ascertain the value of diastase in the feces, one should begin with dialyzed material. By using a suspension of powdered feces we find that the diastatic ferment in different diseases does not have a wide range. It will be necessary to express the results as above and below the normal value to be able to diagnostic from these examinations.

**Tests on the Function of Ovarian Activity.**—R. Keller refers to experiments which prove that ovarian secretion exerted an inhibitory and partially promotive effect on the sympathetic and independent nerve fibres. This fact is supposed to explain their action on other organs. Generally, ovarian secretion has an inhibitory effect on the chromaffin system and an accelerating effect on the secretion of the adrenals, and thereby causes an increase in the sugar output. Contrariwise, a gland having a stimulating action on the chromaffin and the sympathetic would retard action of the adrenals. After castration the glycosuric action of the adrenal secretion was markedly increased. The absence of the generative gland has a stimulating effect on the general system. The frequent symptoms, as heightened blood pressure, heat flashes, dizziness, headache, etc., of the climacteric, taking place after ovarian activity has ceased, are explained by an increased function of the chromaffin system.

**ZENTRALBLATT FÜR GYNAKOLOGIE.**

*September, 1913.*

**Primary Carcinoma of the Fallopian Tube.**—Fonyó calls attention to the fact that carcinoma of the tube is not as rare as is generally thought. He believes that, in many instances where the tube has been removed on account of inflammatory conditions, careful examination would show the presence of malignant changes. Several instances are mentioned in which carcinoma appeared in the operation wound some months later. The author reports two cases and then reviews in some detail the literature bearing upon the subject.

**Changes in the Ovary Due to Repeated Injections of Epinephrin.**—Varaldo states that numerous experiments have shown that there is a functional relationship between the ovaries and adrenals. That when the ovary is removed there is an increased activity of the adrenal with hypertrophy of that organ. Varaldo wished to find out whether ovarian changes could be induced by injecting epinephrin subcutaneously. For this purpose he experimented with rabbits and came to the following conclusions. That during pregnancy the re-
sistance of the rabbit against epinephrin poisoning was increased, but was diminished by castration. Examination of the ovaries showed a visible decrease in size following repeated injections of epinephrin. Prolonged epinephrin poisoning brought about degenerative changes in the ovary, as a result of which the specific glandular structures were replaced by an overgrowth of connective tissue.

The Treatment of Puerperal Sepsis by Intravenous Injections of Distilled Water.—Ilke-witsch first employed injections of 500 c. c. of a 0.01 per cent. silver nitrate solution in distilled water, according to the method advocated by Hume, and obtained very favorable results. Thinking that the nitrate of silver might have nothing to do with the treatment, he employed dilutions as high as one in 30,000, and found that identical results occurred. Since then he has employed the distilled water alone. After the injection of the distilled water, he finds that the blood may show any one of the following conditions: The number of red and white cells increases without any change in the hemoglobin. The number of white cells may increase with a decrease of red cells and hemoglobin, or there may be a decrease in all three factors. Clinically, Ilke-witsch finds that the patients in whom the red cells increase usually recover, while those in whom they decrease generally die. About an hour or an hour and a half after the injection has been given there occurs quite a marked chill, with a rise in temperature. By evening or the next morning the temperature will have fallen to the normal. With the fall in temperature, sweating usually begins. Sometimes there is no chill or fall in temperature. The author has used this method 206 times in the past eighteen months with favorable results.

The Prevention of Puerperal Sepsis Due to Spontaneous Infection.—As lactic acid occurs normally in the vaginal canal, Zweifel makes use of this substance as a cleansing material. By the use of a 0.05 per cent. solution of lactic acid and thoroughly cleansing the vagina for at least ten days, he finds that women with pathological vaginal secretions show no greater tendency to infection than those who are normal. It also seems that as a result of this treatment the pathological bacteria dwindle, while the bacteria normally present increase. In the course of three and a half years the morbidity in those with abnormal secretions diminished from 28.6 per cent. to 7.6 per cent.

LYON MÉDICAL.
September 14, 1913.

Pseudoreduplication of the Second Heart Sound Simulating Mitral Reduplication.—L. Gal-lavardin calls attention to the fact that the traction exerted by the heart on certain pleural or pleuro-pericardial adhesions, at each systole, may give rise to an adventitious sound, which, arising between the two normal heart sounds—generally closer to the second than the first—may simulate a reduplication of the second sound. This adventitious sound can be distinguished from a mitral reduplication in that its seat of maximal intensity is almost always in the region of the apex; that it is the first part of the double sound which appears to the auscultator as the added portion, whereas in mitral reduplication it is the second; that the added sound is superficial and very distinct; that its timbre is always harsh, vibrating, and at times rasplike; that sometimes it is loud enough to be transmitted at a distance; that the time of the adventitious sound varies in its relation to the first and second sounds, and finally, that a cardipulmonary murmur may be tacked on to it, either spontaneously or upon exerting pressure with the stethoscope.

PARIS MÉDICAL.
September 20, 1913.

Clinical Rhinometry.—R. Moreaux describes a simplified procedure for ascertaining and recording accurately the permeability of the nasal passages, e.g., before and after cauterization of the turbinates in hypertrophic rhinitis, removal of nasal mucous polyps, adenoiditis, ozena treated with paraffin injections, etc. The apparatus used consists of a nicked copper plate upon which have been engraved two sets of radiating and other sets of parallel lines, with the distances marked along the former at regular intervals. This mirror is first lightly rubbed with chamois skin, then placed horizontally under the patient’s nostrils, with the point from which the lines radiate in the median line. The patient takes five ordinary full breaths, the moisture from the expired air condensing upon the plate in an area the size of which depends upon the freedom with which nasal respiration occurs, i.e., upon the permeability of the air passages. One minute after the patient’s last expiration upon the plate the margins of the moist area are outlined with ink or chalk. The extent of the area is readily recorded by noting the figures on the radiating lines, or it can be reproduced on diagrammatic sheets printed for the purpose. Curves showing the changes in nasal permeability at different times can also be constructed.

PRESSE MÉDICALES.
September 20, 1913.

Disorders of the Sympathetic System.—Lai-guel-Lavastre terms “sympathetic” conditions characterized by groups of symptoms due to functional disturbances of the sympathetic. Sympathetic disorders, he points out, constitute a borderline subject which overlaps on the pathology of the splanchnic organs, neurology and psychiatry. He divides sympathetics into localized and diffuse, the former being either cervical or thoracoabdominal, while the latter are subdivided into the single (unicval) forms, affecting, e.g., the sensory, circulatory, involuntary motor, secretory or trophic functions, and the complex, consisting of a combination of one or more single disturbances. Among the complex sympathetics may be classified the solar neurasthenia described by Triantaphyllides, Grasset’s vagosympathetic psychoneurosis or psychosplanchnic neuropathy, and the condition described by Galdi as celiac neurosis premonitory to general neurosis of the sympathetic.

September 24, 1913.

Emetine in the Treatment of Hemoptysis.—C. Flandin reports further experience in treating hemoptysis by injecting subcutaneously in the flank or thigh 0.04 gramme of emetine hydrochloride in one
cubic centimeter of sterile water. In about twenty cases in which this measure was used, hemoptysis was regularly arrested, even where copious hemorrhage had been taking place but a short time before. The injection causes temporary pain only in the most sensitive individuals, and its action is not accompanied by any unpleasant side effect. The manner in which the arrest of hemorrhage occurs is quite obscure. It is not due to a lowering of blood pressure, for the author's sphygmomanometric measurements showed the pressure to remain the same; nor could he detect any effect on the coagulability of the blood or the number of red cells, leucocytes, and platelets. Since in severe cases hemoptysis recurs some time after the injection of emetine, the author now repeats the drug twelve hours after the first injection, again the next day, and if necessary on the fourth and fifth days. In but a single case, one of rapidly progressing acute tuberculosis, was permanent arrest of hemoptysis not obtained with emetine.

BRITISH MEDICAL JOURNAL.
October 4, 1913.

Report on Two Hundred Cases of Ringworm Treated with X Rays.—F. Emrys-Jones considers this the best and much the quickest method of treating this disease, particularly when the disease is well established and extensive. He uses the single dose method; that is, but one exposure is given to any portion of the infected area unless, for some reason the first exposure has been incomplete. Nervousness and the patient’s inability to keep still, lack of perfectly suitable tubes, and inexact centering of the tube in the holder are the commonest reasons for having to give a second dose. He has never had an x ray burn, although ninety-three of the cases were infected over the entire scalp. He uses a twelve inch coil equipped with a dipper, brake and tachimeter for regulating the number of interruptions. An automatic cut-out switch is used in circuit with this, so that a definite number of interruptions can be given with no danger of accidentally giving an overdose. A Sabouraud pastille is used for the application.

Nondiabetic Glycosuria.—A. E. Garrod says that, as yet, there is no adequate definition of diabetes and that, therefore, no sharp line can be drawn between diabetic and nondiabetic glycosuria. He, therefore, adopts a classification based upon clinical data for his discussion. The first type of nondiabetic glycosuria is that prematurely termed renal glycosuria. In this there is an excretion of a small daily amount of glucose in the urine, but there is no hyperglycemia; in fact there may be a reduction in the sugar in the blood below the normal percentage. The most striking feature of this condition is the fact that the daily amount of sugar excreted in the urine is very constant and is not affected by an increased carbohydrate intake. The condition suggests the existence of an abnormal renal permeability to sugar, similar to the experimental phloroglucon glycosuria. A second class of nondiabetic glycosuric patients is found among the middle aged, who occasionally pass sugar in their urine. In such patients there is probably an actual reduction in the carbohydrate tolerance, but it is so slight as to give rise to glycosuria only at those times when the patient has considerably overeaten of starchy foods. Such a condition is known to be compatible with many years of life. There are other cases, ones which are true temporary glycosurias, in which the sugar tolerance becomes normal between glycosuric phases. Those cases of temporary glycosuria which are met with in the course of infections such as pneumonia, scarlatina and secondary syphilis, and associated with phlegmonous conditions seem also to belong clinically to the group of nondiabetic glycosurias, though it may be that in such conditions there is some implication of the pancreas. If so, they are of the essential nature of true diabetes. Such is probably the case in mumps, the only infectious disease which is known to involve the pancreas. There seems to be excellent reason to regard the islands of Langerhans as probably the dominant, if not the only, controllers of carbohydrate metabolism. It can scarcely be doubted that the pancreas is subject to minor ailments as are the salivary glands. It is therefore not impossible that such minor lesions may often be the causative factors in the production of the temporary glycosurias. Hyperactivity of both the thyroid and pituitary glands, and possibly of the suprarenals, causes, at times, a nondiabetic glycosuria, due, probably, to a disturbance of the interrelation between these glands and the pancreas. Among other forms of nondiabetic glycosuria may be mentioned those from shock or excitement; disease of the brain; tuberculous meningitis; and many drugs and toxic substances. It is often almost impossible to distinguish between a truly nondiabetic glycosuria and a true diabetes, and a judicious restriction of the diet in any case can do no harm, while, on the other hand, a continued unrestrained diet in such mild states may possibly entail irreparable damage to the patient.

The Heart as Affected by the Stomach.—Walter Broadbent directs attention to the close relation which exists between these two organs, both anatomically and through mutual innervation through the vagus. Distension of the stomach by gas or other cause may start a vagus reflex, or the direct upward pressure of the stomach may irritate the heart and give rise to palpitation, extra systoles, or even to pseudoangina pectoris. It may also greatly aggravate an existing tendency to paroxysmal tachycardia, or may even precipitate an attack of true angina. In certain forms of valvular disease, especially when there is considerable dilatation of the right ventricle a rise in the height of the diaphragm due to the distention of the stomach with gas or food may cause serious embarrassment to the circulation. In all such cases attention should be directed to the stomach as well as to the heart, and in some the treatment of the digestive disorder is quite as important as that of the heart itself.

LANCET.
October 4, 1913.

The Work of the Medical Profession in India. — In this address John P. Hewett illustrates in a striking manner the enormous benefits to mankind that have resulted from animal experimentation.
In the first place the death rate from smallpox was more than three times as great thirty years ago, before the general vaccination of natives, as it is now. It would now be much less had not the English opponents of vaccination worked to make the people of India hostile to the practice which has brought them such great benefit. The results of the inoculation against plague with the prophylactic vaccine of HAffkine have been no less striking. In a single instance in a factory with a roll of between six and seven thousand, 5,046 of the hands were inoculated against plague. In this group there were only nine fatal cases, six of which occurred as the result of an attack within ten days of inoculation. Among the small number of un inoculated there were 178 deaths. The general use of antityphoid inoculation among the British troops has reduced the mortality from more than ten per mille to 0.17 per mille at the present. Animal experiments have yielded excellent results in the manner of reducing the dread mortality from the bites of venomous snakes, particularly in the case of the cobra and Russel's viper. The prompt administration of antivenins will prevent the bites of these two snakes from being fatal. There are several other snakes the bite of which is deadly, and there is need for considerable study to provide the means of combating the effects of their bites. Perhaps nowhere has the prevalence of rabies so great as in India. Here the recent establishment of a few Pasteur institutes has enormously reduced the mortality from this disease. Hewett remarks that "experience in India, as elsewhere, proves conclusively that operations on animals have afforded untold benefits to the human race. Performed with the utmost care by skilled surgeons, they are rendered almost painless through the use of anesthetics, and are followed by a drug softened death. As instances of cruelty to our dumb friends, how can they possibly be compared to the limitless sufferings imposed on beasts of burden and other animals on whose aid mankind depends in India and many foreign countries?""  

Hemiplegia Following Syphilis.—Murdock Mackimnon records four cases in which there developed more or less extensive plegic phenomena as the result of syphilitic lesions in the brain and surrounding membranes. In three of the cases the lesions developed within nine months after the primary infection, in the fourth the interval was about four years between infection and the first cerebral symptoms. The characteristic features of such early cerebral syphilitic phenomena are their great tendency to be multiple, a lesion in one area being followed by a lesion in an entirely different one. In one of the cases there was a hemiplegia on the right side, which cleared up under treatment, only to be followed subsequently by a similar hemiplegia on the left side. The second characteristic of these lesions is the readiness with which they yield to anti-syphilitic treatment.  

Acute Epididymoorchitis Due to Bacillus Coli. —W. P. Bonner's patient "strained" himself by lifting some twenty days before his admission to hospital. The "strain" was accompanied with extreme but transitory pain. Four days later frequency of micturition developed. Two days after this he began to have pain in the right testicle. There was no history or evidence of his ever having had gonorrhoea. On examination he was found to have an acute epididymitis and orchitis, with tenderness and slight swelling along the cord and vas deferens. The prostate and seminal vesicles were not tender nor enlarged. His urine contained considerable pus. The epididymitis progressed so as to require surgical treatment, though when opened no true pus was found. Cultures made from the urine, prostatic fluid, and the epididymis all showed the bacillus coli. There was marked destruction of the tubules of the epididymis, fragments of which could be seen in the material removed on incision. General and local measures, combined with the administration of coli vaccine, brought about a complete recovery.  

A Neuromatous Myoma of the Mesentery.—The boy, whose case Peter Paterson here reports, was nine years old and poorly developed both mentally and physically. About five months before, he had been operated upon for the removal of his appendix, which was believed to have been the cause of his acute abdominal symptoms. This organ was not found to be materially diseased. After leaving the hospital he had frequent severe attacks of abdominal pain, accompanied by vomiting and constipation. There was no fever. On examination a smooth, tender mass was felt almost free in the abdomen. This was removed on operation, having been found to lie encapsulated in the mesentery. The child made a good recovery and has since been free from symptoms. The tumor was 0.5 centimetres long by four centimetres in the short diameter. Oval in shape and smooth, it was found to have a soft reddish centre, while the outer part appeared much like a fibroma. Microscopic section from the centre showed it to be composed almost wholly of medullated nerve fibres and a few ganglionic cells. Parts nearer the surface showed the fibres in ill defined bundles, bound together with fibrous tissue, and containing strands of smooth muscle. These latter increased as the capsule was approached, where the tissue was almost wholly muscle.
PITH

The New Immigration as It Affects Orthopedic Surgery.—Wallace Blanchard says that a larger number of severe rachitic deformities of the legs have been rapidly corrected by bloodless osteoclasis in Chicago than in any half dozen other cities in the world. The records of the free orthopedic hospitals and dispensaries there show that the new immigrant gives them eight times their normal ratio of rachitic deformities, and twice their normal ratio of scoliotic deformities, and twice their normal ratio of tuberculous deformities. The emigrant woman has nearly twice as many children as the American born woman, statistics showing 4.7 against 2.9 per cent. Bad rachitic deformities, tuberculous joints, and scoliosis in the young of these new emigrants mean a large element of helpless pauperism for the future. If the government and the community could be roused to the necessity of caring for the welfare of the immigrant mother for the first year or two in her new home, it would be a great uplift for the future American citizen.

Functional Test (Phenolsulphonephthalein) of the Kidney in Scarlet Fever.—M. Fishbein states that the test has now been made on many hundred cases, and in over forty post mortem examinations have confirmed the presence of conditions suggested by the test results. In the cases reported in the paper the dye was injected intramuscularly. The bladder was emptied, and specimens collected after one hour and after two hours. The colorimeter used was that described by Cabot and Young, consisting of a series of twenty tubes, containing five, ten, fifteen, etc., per cent. of the dye. The author's conclusions are as follows: There seems to be a general lowering of the renal function during the later stages of scarlet fever. In nearly all uncomplicated cases examined, from the third to the fifth week a total output averaging fifty-five per cent. was observed, as compared with a normal of from sixty-five to eighty-five per cent. In the instances of acute nephritis an increased output was observed in two, a lowered output in one. In several instances in which headache and nausea occurred, although no albumin was found in the urine, the test showed a decreased function of the kidney. The practical value of the test as aid in the treatment of this disease, in which nephritis is so common a complication, is apparent.

The Whitman Operation for Talipes Calcaneus Paralyticus.—J. P. Lord reports that during the past year he has done the Whitman operation twenty times upon eighteen patients, and the immediate results have been so gratifying that he endorses the procedure with enthusiasm. It is his observation that too few surgeons employ this method of radical relief, and he therefore desires to aid in its popularization through the report of the results of his experience. The operation, moreover, has a wider range of application than for calcaneus alone, and may be modified by various tendon transferences to meet special indications. In brief, the Whitman operation consists of: 1. the removal of the astragalus; 2. the freeing of the malleoli and the preparation of a new articulation; 3. the transplantation or resuture of the peronei tendons; 4. the backward displacement of the foot; 5. the fixation of the foot in equinus. In the after-treatment a fixation plaster is kept in position for
about four weeks; then an ambulatory plaster is used for about five months. As to the results, causus and lateral instability are corrected, the backward displacement checks dorsal flexion by direct contact and by change in leverage, and the power of the transplanted muscles is made more effective. This operation is the only effective procedure for an advanced deformity, and it is also indicated in early cases as a preventive of progressive deformity. The typical or stereotyped operation is not always to be adhered to, because indications vary; especially when the operation is performed to ameliorate conditions other than the one for which the operation was originally devised.

Results Obtained in the Nonsurgical Treatment of Tuberculosis of the Joints.—H. W. Orr says that some years ago he began to be impressed with the fact that patients with joint tuberculosis who had previously been operated upon were, in general, much more seriously disabled, and that the active stage of their disease was much more prolonged than in the advanced cases in which surgery had not previously been resorted to. Wishing to compare, in patients operated upon and those not operated upon, the periods of active disease processes and the amounts of resultant deformity, he has recently checked up a series of fifty patients of this character, of whom he had satisfactory records for the purpose. The results of this study show a wide margin of advantage for the patients not operated upon. Operation in adults especially is perhaps most frequently resorted to as a time saving expedient. In the patients studied this proved to be a fallacy, as these patients were disabled much longer than the average of patients conservatively treated. All our experience with bone and joint tuberculosis teaches us that a large proportion of good results may be obtained by conservative treatment when the diagnosis is made early and the treatment carefully carried out. It is unquestionable that careless diagnosis and ignorance on the part of some overenthusiastic surgeons of the admirable results obtainable by efficient mechanical treatment prompt them to do operations which might better have been left undone. The author's own experience has been that equally good results may be obtained even in those patients requiring a minor surgical procedure, even in late cases, when it is combined with careful mechanical treatment and strict surgical aftercare.

MEDICAL RECORD.

October 11, 1913.

The Modern Treatment of Tabes.—Joseph Collins expresses his belief that tabes is a syphilitic disease in every instance, and discusses the treatment under three headings: Causal therapy, symptomatic therapy, and plan of treatment. Under the first he says that the treatment of tabes is far more satisfactory now than it was before the advent of salvarsan, though salvarsan alone does not seem to bring about the degree of recovery that salvarsan plus mercury does. If neosalvarsan is used instead of salvarsan, the intervals between the administrations should be less. In addition to antisyphilitic treatment, many measures are utilized which are directed, not so much against the cause of the disease or the disease process, as against the inroads which the disease makes upon the patient's vitality. Among these are electricity (galvanism and the high frequency current), massage, hydric measures, counteraction, nerve stretching, diet, climatic consideration, medication, and reeducation of purposeful movements. As to the ineradicable belief in the rank and file of the profession that tabes is a "tertiary" manifestation of syphilis, and that therefore potassium iodide, which is regarded as a "specific" for tertiary manifestations, should be given to tubetics, the author says that those who, like himself, are daily witnesses of the baneful effects of the iodide will continue to protest against its use whenever occasion offers. There are symptoms of tabes which demand mitigation or relief, such as pain and paresthesias, vesical and rectal incontinency, gastric and laryngeal crises, arthropathies and perforating ulcers, hypotonia and ataxia, ocular palsies and insomnia, and to ameliorate them is an important part of the physician's problem. The most important factor of the treatment, next to the administration of the substances which destroy the cause of the disease, but one that is almost uniformly neglected, is the general nutrition of the patient. Possibly of even equal importance with the causal treatment of tabes is the plan of treatment. Nothing does so much injury to the patient or his prospects of recovery as a pessimistic attitude on the part of the physician. In the majority of instances it is advisable for the latter to explain to the patient fully, and in a way that will not alarm him, just what the disease is, that it need not materially shorten his life: that from fifteen to twenty-five years of comparative efficiency may be vouchsafed him, and that, with the disease vigorously combated, a certain degree of functional preservation and restitution may be anticipated. It cannot be expected that every case of tabes will justify such prophecy, but the majority of instances will.

The Use of Tuberculin in the Diagnosis of Obscure Conditions in the Genitourinary System.—Edwin Beer emphasizes the importance of this very useful and much neglected aid in the diagnosis of tuberculous conditions in the genitourinary tract. He first refers to the evidence in favor of the influence of the tuberculin reaction, and then cites some illustrative obscure cases of renal, prostatic, and testicular diseases in which tuberculin definitely assisted in making the diagnosis. He also refers to the experience of some others along the same lines, and states that all the more recent evidence goes to show that this drug is not dangerous when carefully used under proper restrictions. In his work he employs imported "old tuberculin," and this is diluted so that five drops are equal to half a milligramme. He by no means recommends the use of tuberculin as a routine procedure in genitourinary disease. On the contrary, he makes it a rule to employ every available means of diagnosis before resorting to it.

The Paroxystic Attack of Metatarsal Pain (Morton's Metatarsalgia).—C. K. Austin regards it as practically certain that this condition is due to the nipping of one of the branches of the external plantar nerve in the fourth intermetatarsal space, owing to spreading of the transverse arch, which allows the second and third metatarsals to sink down. He relates a case and presents a radiograph
of the patient's foot, which shows no lesions. Treatment is either palliative or radical. In the first instance an attempt is made, by the use of tight bandaging or of felt pads or leather insoles so fashioned as to bring pressure upward behind the heads of the second and third metatarsals, to prevent the foot from widening when weight is thrown on it, and the arch from lowering. Radical treatment consists in excision of the fourth metatarsophalangeal joint, with its adjacent soft parts. In the case reported the condition has apparently been quite relieved by a well-fitting shoe and a bandage passing several times around the transverse arch.

A Study of the Bacteriemia in Pneumococcus Infection of the Rabbit.—G. A. Rueck studied the bacteremia following intravenous inoculation with the pneumococcus in forty-two rabbits, in series or in sets of from one to six animals, and in summarizing the results of his experiments states that it is evident the course of pneumococcus infections varies greatly even in the rabbit, although equal doses of the same organism are used. The rabbit's tissues, therefore, have some antibacterial properties. Large doses of the pneumococcus cultures or the more virulent pneumococci neutralized these antibacterial substances in the body tissues, and the bacteremia progressed immediately to fatal issue. The temperature may rise, or it may fall; but this apparently had no effect on the bacteremia in these animals. Moderate doses of less virulent pneumococci give rise to a longer course of infection, with fluctuating bacteremia and temperature. These prolonged infections also are often fatal, though occasionally recovery takes place. In the experiments there was no very definite evidence of a retarding influence of an elevated temperature upon the growth of pneumococci in the rabbit. A temperature of from 105° to 106° F., which retards or arrests pneumococcus growth in the test tube, and which may also inhibit growth in the rabbit's tissues, does not necessarily diminish the bacteremia.

---

Proceedings of Societies.

MEDICAL ASSOCIATION OF THE SOUTHWEST.

Eighth Annual Meeting, Held at Kansas City, Missouri, October 7 and 8, 1913.

The President, Dr. W. T. Wooron, of Hot Springs, Arkansas, in the Chair.

Prophylaxis of Syphilis and Professional Ethics.—Dr. Alfred Schalek, of Omaha, said that syphilis must be attacked in two directions, in its relation to society and to the individual. Syphilis was contracted directly by sexual contact and indirectly through a virus carrier. Sexual functions were indulged in legitimately in marriage and promiscuously outside of it. Prostitution contributed the greatest factor in spreading infection. It was only a question of time before every prostitute became diseased. The problem how to deal with prostitution was not solved. Official regulation had proved a failure wherever attempted. Absolute suppression was the only relief. While seemingly an Utopian dream, it was feasible with the honest cooperation of everybody concerned. It could not be achieved by the closing of the bawdy houses alone. It necessitated measures to stop all other sources leading to prostitution, such as strict enforcement of the white slavery laws, to be inaccessible to the poor. When the time came that syphilis was looked upon only as a pathological condition, in no way different from others, when its stigma of disrepute had been removed, when our therapy would destroy the microorganisms and eliminate their toxines, and not only secure a symptomatic but a real cure, our ambition to make syphilis a disease of the past would be realized.

Dr. William Frick, of Kansas City, Missouri, who opened the discussion, emphasized the fact that a great many cases of syphilis were innocently contracted. He recalled the case of a young woman in whom a chancre on the upper lip developed. How it occurred was a mystery for some time. It was finally learned that she was having her teeth repaired, but this particular dentist was not clean about his instruments, and during the times of repair of the teeth injury was done to the upper lip, and about the proper length of time a chancre developed. She had a secondary eruption, not knowing what it was. This was one phase of the subject that deserved great stress. He had seen quite a number of such cases.

Dr. J. D. Kernodle, of Boyle, Oklahoma, believed ignorance was at the bottom of the trouble. There was not a boy or girl who did not know right from wrong, but they did not know the tremendous consequences following a wrong. They needed education along these lines.

Dr. E. H. Martin, of Hot Springs, Arkansas, said if every house of prostitution was raided and the inmates all treated regardless of symptoms, there would be less danger than now. If we admitted we could cure syphilis, we would admit that the best method was prophylaxis. He stood almost alone in believing from observation and practical experience that salvarsan would cure syphilis. He had had more than fourteen cases of reinfection after having treated cases with salvarsan. He had one patient who had had three primary lesions in eighteen months. His method was to give one dose of salvarsan in proportion to the patient's weight every week until there was absolutely no reaction from the dose. In the secondary stage, after the chancre colony was broken up, and the organisms were expelled, after the chancre had softened, the average number of doses was three, given ten days apart.

Dr. R. H. T. Mann, of Texarkana, Texas, asked if it was possible to eradicate syphilis from America? It was, and that such a thing could be done and done only when the medical profession awakened to its full responsibility and got the assistance of various communities and State governments. Whether this task could be performed in this generation, or whether it would fall upon future generations to drive syphilis out of America, depended wholly upon the activities of the physicians now living, but it was a task that could be accomplished. The medical profession owed it to humanity to eradicate syphilis from this country.
Dr. E. G. Mark, of Kansas City, Missouri, stated that in the prevention of venereal disease we must take the stand as physicians that prostitution could not be eradicated. It was the oldest profession in the world. You could not eradicate it, but you could segregate and control it. It had been brought to our attention in the last few weeks that Minneapolis, Chicago, and other cities had eradicated prostitution, but the facts were it was not so. With proper segregation, proper inspection, venereal diseases could almost be eradicated; but prostitution could never be suppressed.

Dr. Ross Grosshart, of Tulsa, Oklahoma, said that in doing away with the segregation of prostitutes, they were driven into various districts and were living in the midst of respectable people. Venereal diseases and their dangers should be taught to the pupils of high schools, and when this was done sexual evils would be lessened and much done toward the wiping out of syphilis.

Doctor Schalek in closing said that he did not agree with Doctor Mark regarding the suppression of prostitution. Fifteen years ago he read a paper in which he stated that the suppression of prostitution was impossible, but he did not believe it now. He believed it was possible to wipe out prostitution. Most women were driven to prostitution; others wanted to lead a lazy life; they wanted to enjoy luxury, but these were few in number as compared with those who were driven to it for money.

The Operative Treatment of Glaucoma.—Dr. R. H. T. Mann, of Texarkana, Texas, said that the conjunctival flap should be made large. Care should be taken not to let the trephine enter the eye too far back. Should the piece which had been removed with the trephine fall into the anterior chamber, this could either be removed or left in the anterior chamber, as it did no harm when it was left there. It seemed with a permanent opening in the eye, that infec- tion might take place, but so far as the records went there was no danger of this. He did not believe that any one of the operations for glaucoma would be the operation permanently adopted for the cure of chronic glaucoma. He felt sure, however, that the operation finally adopted would be an operation which produced a filtering cicatrix, and until a better operation was devised the Elliott operation should be the one adopted in chronic glaucoma.

In the discussion which followed, Dr. C. L. Williams, of Topeka, Kansas, said as to this trephining operation for chronic glaucoma, the consensus was in making an opening through to include a portion of the sclera and a portion of the iris, going down through the cornea and corneoscleral incision, and by a mixture of the different formations of tissues permanent drainage would be established, thus relieving tension. However, we had not sufficient data at present to know the permanent value of this operation in chronic glaucoma.

Dr. J. Ellis Jennings, of St. Louis, Missouri, said he had had a set of these trephines sent to him from London and had done four or five of these operations recently. He had had one case of late of a very rapidly advancing chronic glaucoma in which he did the LeGrange operation and removed quite a bit of the sclera, and that case had turned out beautifully. He had to use eserine in that eye for several months, but since that time no eserine had been used. The tension was fine and the sight had improved. This trephining operation was very delicate, but one from which we could hope for very beneficial results.

Dr. Joseph S. Lichtenberg, of Kansas City, Missouri, said glaucoma was not a disease, but a symptom, and since we did not know what glaucoma was, all this work was, more or less, done from the standpoint of treatment of the symptoms, and not from a clinical point of view. The operation of trephining was simple and efficacious.

Tumor of the Nasopharynx.—Dr. C. L. Williams, of Topeka, Kansas, said the points of interest he desired to emphasize were: 1, persistent growth in the nasopharynx, with a tendency to occur when removed; 2, frequent hemorrhages difficult to control and threatening the life of the patient; 3, the difficulty in arriving at the true pathology of this tumor.

Dr. Joseph C. Beck, of Chicago, Illinois, who opened the discussion, said the tumor was undoubtedly a small spindle cell sarcoma. These growths arose from the posterior naris in the region of the ostium tube and extended to the postnasal space and also into the nose. The literature was teeming with reports of these cases, so there was nothing to be said in regard to that. The method of removal of these tumors was that of Pynchon, of Chicago. When the doctor removed the adenoids, if he had made an examination it would have shown the sarcomatous nature of the tumor.

Dr. W. T. Black, of St. Louis, Missouri, said it looked very much like a small spindle cell sarcoma. The fact that the doctor was able to shell it out so easily was another indication that it was a sarcoma. We knew that fibroma of the nasopharynx was a difficult tumor to remove.

Dr. R. H. T. Mann, of Texarkana, Texas, said that a good many years ago he operated on five or six of these tumors in one year. One tumor was a very large fibroma. If one knew he was going to have a severe hemorrhage, it was best to ligate the external carotid artery on the side on which the tumor was situated. If this was done before the operation, one would have little or no trouble from hemorrhage.

Dr. M. F. Jarrett, of Fort Scott, Kansas, said he had one of these cases at his office yesterday; he had been treating the patient for three or four months. It was probably six months since he removed the last adenoid tissue. He did not examine the tissue under the microscope, but supposed it was the adenoid tissue. The patient was thirty-five years of age. The growth had returned slowly. The slowness of the growth led him to think it was malignant.

The Complete Removal of the Tonsil in Its Capsule (Sluder Method) by Means of a New Tonsillotome.—Dr. J. Ellis Jennings, of St. Louis, Missouri, said that Sluder had described a method of removing the tonsil in its capsule complete by means of the guillotine or tonsillotome. The essential and distinctive feature of this method was removing the tonsil completely out of its normal bed and upward onto the eminence of the lower jaw produced by the last molar tooth, and the util-
ization of this prominence in putting the tonsil through the aperture of the guillotine. For this operation a tonsillotome of great strength and leverage power was essential. Doctor Sluder used a MacKenzie guillotine which he had modified by doubling the thickness of the shaft, shortening its length, and making the handle longer. The blade was driven home by pressure with the thumb. He had designed an instrument for this operation with a ring knife to cut on the pull. The instruments necessary for the operation were the tonsillotome, the mouth gag, tongue depressor, several sponge forceps, and tonsil hemostat.

The Tonsil, with Especial Reference to the Sluder-Ballenger Operation.—Dr. Eugene Dixon, of Oklahoma City, said the Sluder-Ballenger operation could be done with either local or general anesthesia; personally he preferred the latter, and would only mention the local in a way of warning against the too concentrated epinephrin solution, as many sudden deaths were being reported from tonsillectomies by its use, but it was safe with the weaker solution and just as effective in controlling hemorrhage. In this operation above all others, it was essential to have a competent anesthetist, one who knew at all times just in what stage of anesthesia his patient was, as it was very important not to begin the operation until the patient was thoroughly anesthetized and to have given 1/200 grain of atropine sulphate, one half hour before the anesthetic was started. Following the Sluder method of removal of tonsils, there was less trauma, and consequently less cicatrical tissue. If one examined his cases three months after operation he would not find both pillars bound together, obliterating the sinus tonsillaris, nor would he find contractions and shortening of the muscles interfering with the action of the throat and soft palate, thus putting the singer out of business. If those who insisted upon using the angular knife and snare would follow their patients up for several months and make a record of the condition of each throat they would soon be convinced.

Surgical Treatment of Tonsillitis.—Dr. T. L. Higginbotham, of Liberal, Kansas, said that tonsillitis was just as much a surgical disease as was appendicitis, a carbuncle, an osteomyelitis, or a blind infected eye, and should receive the same determined and energetic treatment as the conditions named, and just as early, that the dangerous complications might be prevented. Since November, 1900, he had operated in 142 cases of tonsillitis, in all stages of inflammation from the onset to bilateral quinsy, and with the results obtained he felt perfectly free to condemn methods that were inefficient and deceptive. With the vast number of men doing the perfected enucleating operation, this method of treatment could be extended to the most remote rural districts, just as was emergency surgery in other lines, and in the meantime assume obligations that were ours as well as elevate the standard of our calling.

The discussion was opened by Dr. A. E. Hertzler, of Kansas City, Missouri, who said he had not found a general practitioner yet who was not enthusiastically in favor of removing the tonsils soon after the beginning of the disease. He had been skeptical as to the correctness of the reports regarding the sudden dropping of the temperature and rapid convalescence. It would seem that laryngologists had been behind the general surgeon in recognizing the acute lymphatic inflammations in this region as a proposition for prompt and radical surgery. He had a number of specimens of these acute tonsils and it was exceedingly interesting to lay them side by side with acute appendices removed in the early stages of appendicitis.

Dr. Joseph C. Beck, of Chicago, Illinois, said that with his tonsillotome Dr. Jennings removed, but did not cut the tonsil. In a paper he had described the method of using Mathieu's tonsillotome, and the technic did not vary one particle so far as the use of the instrument was concerned from that described by Doctor Jennings. He did not agree with Doctor Hertzler. The anatomical structure of the tonsil was different from that of the appendix; it did not matter at what time one operated on the tonsil, but it did on the appendix.

Dr. E. M. Seydell, of Wichita, Kansas, said in a few instances he had removed acutely diseased tonsils. Patients had come to him and wanted the work done at once, and he had taken the chances of removing their tonsils, but at times had felt sorry he had taken these chances for fear of Ludwig's angina developing.

Dr. D. L. Shumate, of Kansas City, Missouri, had operated in acute tonsillar cases when the patients came to him from the outside and had not seen any bad effects from it. In removing tonsils, if one removed all tonsillar tissue, one would have good results, no matter what method he adopted.

Dr. F. B. Tiffany, of Kansas City, Missouri, said he had had the privilege of studying with Lennox Browne and Morel MacKenzie many years ago, and they never hesitated to operate when the tonsils were acutely inflamed. That had been his practice and he had not seen any bad results from it.

Dr. J. F. Shelley, of Elmdale, Kansas, said he had been in practice for twenty years and had hesitated to remove tonsils when they were acutely inflamed and when there was slight catarrh of the mucous membrane. In removing the tonsils when they were acutely inflamed one opened the raw surfaces for infection that came from surrounding tissues, and he was laying himself liable to a damage suit. He would not do it under any circumstances.

Dr. C. L. Williams, of Topeka, Kansas, said it had been his practice in the last two or three years to watch the effect of operating in acute tonsillitis, or when patients were getting over the attack, and he was firmly convinced that if one operated in an acute case the wound would take longer to heal and it kept the patient away from his work longer.

Dr. William E. Jones, of Oklahoma City, Oklahoma, said that at first he had some fear in operating in acute cases of tonsillitis, but with increased experience that fear had passed away. While the symptoms in a few cases were alarming from operating in acute cases of tonsillitis, they soon subsided.

Surgical Constipation.—Dr. A. L. Blesh, of Oklahoma City, Oklahoma, said that aside from various stenoses, congenital or acquired, constipation had principally to do with the colon, or (to better express his meaning) the colon had most to do with constipation. Coprostasis was the fons et
**LETTERS TO THE EDITOR.**

**Operative Treatment of Constipation.**—Dr. W. J. Frick, of Kansas City, Missouri, stated that the operative treatment of constipation was indicated when some degree of organic obstruction of the intestine existed. He was not an advocate of surgical interference in this condition except after all efforts at a medical cure had failed, and the patient was threatened with a permanent invalidism. Undoubtedly there were intraabdominal and intrapelvic conditions, purely surgical in nature, which were clearly responsible for the constipation. He referred to the recently much talked of developmental bands, membranes, adhesions, etc., with the resulting kinks in the intestinal tube, tumors in the intestinal wall, tumors of other abdominal and pelvic organs, and displaced viscera, many of which might be the direct or indirect cause of constipation by inhibiting in some degree the normal peristalsis of the gut. Such cases were clearly operative, as there was no other method of dealing successfully with the primary cause of the trouble. Concerning the bands, membranes, adhesions, and kinks as described by Treves, Joneesco, Jackson, Lane, and others, we could not yet be certain whether they were the cause or the result of constipation. According to the available evidence, it would seem that they were the cause rather than the result since the most recent researches appeared to support the theory that they were developmental in origin rather than the result of inflammatory processes. But that they might bear neither causal nor resultant relationship to constipation was shown by the clinical experience of competent observers. Certainly, much improvement followed the division of these structures in some cases; just as certainly this treatment had given not the slightest benefit in other cases.

Another of the causes of constipation was the result of chronic pelvic peritonitis. He had in mind the fixation of the pelvic colon to the pelvic floor or to the rectum. Tuttle recommended in this condition division of the adhesions and, if necessary, the fixation of the pelvic colon to the abdominal wall to prevent a recurrence of the angulation of the gut. In a series of fifteen operations of this kind he declared there was no case in which bowel movements were not free and comfortable after operation. In this series the operation was not always done solely for constipation; however, all of the patients operated upon for no other reason than constipation were completely relieved.

Some fibroids of the uterus, retrodisplacements of the uterus, and tense cysts were capable of exerting such pressure upon the pelvic colon as to cause difficult, painful, and inefficient defecation. After removal of the tumor, or correction of the displacement, these patients recovered from their constipation.

Among other short circuiting operations was one done for exclusion of the splenic flexure, that is, anastomosis between the ascending limb of the transverse colon and the descending colon. Gant successfully established an anastomosis between the pelvic colon and the rectum after a division of the adhesions and fixation of the prolapsed pelvic colon to the anterior abdominal wall had failed. Mr. Lane was very enthusiastic about the more radical operation, colectomy. It was safe to say that this operation relieved all the trouble that might have existed in the colon; however, the removal of the colon was a formidable operation and was not without danger even in the hands of such a great abdominal surgeon as Mr. Lane. It was not an operation for one who had not had a large experience in abdominal surgery.

It must ever be borne in mind that all short circuiting operations of whatever type were contraindicated in cases in which the cause of the trouble lay distal to the lower portion of the pelvic colon. In such cases ileosigmoidostomy could not relieve, but on the contrary might even aggravate the trouble.

*(To be concluded.)*

**SENSE OF SMELL AS AN AID TO DIAGNOSIS.**

*ZURICH, October 6, 1913.*

**To the Editor:**

Dr. Robert Coughlin’s article under this title, published on July 17th, has many points of interest and some open to criticism. Perhaps as regards the latter it would be as well to speak of the sense of smell as a *confirmation* of diagnosis—the proper clinical diagnosis should precede the other. Diagnoses of the moment are liable to have a very considerably need of correction afterward.

Dr. Coughlin speaks of the odor of the breath and the sputum in tuberculosis; he says nothing of the odor of perspiration.

For many years I have noticed a *pungent acid* odor of the perspiration of the body, especially also in the armpits,
but not from the feet of tuberculous subjects—or to speak more correctly, in patients suffering from active tuberculosis.

If patients are very careful about their personal cleanliness, and make ablations every day and have warm baths once or twice a week, this odor is often absent, but yet, even then, it is sometimes present. If they are not so careful about their personal hygiene, I can detect the odor in a majority of cases of active incipient tuberculosis, so much so that in the last two or three years I have made a note in my register "specific odor." I have never detected it in any other disease than pulmonary tuberculosis, and I suppose it to be due to certain specific toxins eliminated by the skin. As to prognosis I have nothing to say, as nearly all patients in my opinion have a bad beginning (Turban)—recover under proper treatment, dietetic, hygienic, and, if necessary, climatic. It might be worth while to follow up these observations on a larger scale.

Theodore Zangger, M. D.

Book Reviews.

[We publish full lists of Books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Until one glances through such a book as this he does not realize the universality of the vicious circle. It is clearly shown how such circles tend to arise and to continue indefinitely unless some measure is adopted that will break the circle.ժes vicious circle, for example, in the following generic groups, organic, mechanical, infective, nervous, chemical, those due to imperfect repair, and artificial. In this latter class are included those circles resulting from the misuse of cathartics, alcohol, morphine, and various other drugs. The chapters dealing with the breaking of the circle by art and by Nature are full of interesting points and show how harm may be done by too much interference with the processes of Nature. A study of this volume would tend to make one much more familiar with the correlation of pathological conditions to clinical symptoms and in that way would be a valuable aid in diagnosis.

The fourth edition of this little treatise which aims to be particularly an aid to diagnosis and treatment, has been somewhat enlarged by the addition of several new chapters. It is by no means a compend and if the book were printed in larger type, on heavier paper, it would present a more dignified appearance, and conform to the modern demand for a readable page. In the article on Infant Feeding there is a surprising admixture of the new and the old. There are a bewildering number of methods of feeding described, and while they show a familiarity with the subject, it is difficult to be confusing to the reader who may not be in a position to winnow the wheat from the chaff. He would give the impression that the laboratory method is the one extensively followed in America. Modern methods of treatment which have proved of value are, as a rule, described, and the treatment is commendable detail. The reviewer feels, however, that a form of treatment such as direct blood transfusion in hemophilia neonatorum, for example, should outrank and precede the recommendation of a drug such as the perchloride of iron which he advises. The new article on cerebrospinal meningitis is well written and the use of Flexner's serum is unqualifiedly recommended. The author's statement that salvarsan has not been successful in the treatment of cerebrospinal meningitis is fully accepted. The book is more meritorious than the ordinary student's compend, and will be of decided help to the student in this branch of medicine.

The fourth edition of this standard textbook fulfills the aim of the author to keep abreast of the rapid advance in neurology which has been made since the publication of the third edition, some three years ago. In particular might be mentioned the new material which has been added to the chapters on poliomyelitis, syphilis of the nervous system, and tumors of the brain. With this addition, the third part of the book, that dealing with functional diseases, that the most additions have been made, compensating for a possible deficiency of the last edition: Thus, psychasthenia is considered in a chapter by itself; various forms of psychotherapy including suggestion, hypnotism, and psychoanalysis are discussed; and in the chapter on hysteria the varying theories of Babinski, Janet, and Freud are presented. A pleasing feature of the work lies in the fact that, while due consideration is given to the recent literature on these subjects, the work is not in a large measure the personal experience of the author.

As the author has introduced into this second edition an importance of which the book has been published since 1900 it is considerably enlarged. First taking up the acute post-hemorrhagic anemia, Professor Lazarus goes into much detail concerning the changes in the blood and in the organs. The transfusion methods of treatment are dealt with quite fully. Under the heading of simple chronic anemia come those due to hemorrhage, those resulting from poor hygiene and insufficient food, those accompanying or following other diseases, and those due to poisonings of various kinds. To progressive pernicious anemia is given by far the greatest space. The author at the start lays emphasis on the point that this condition is not a definite entity, but is a common grouping of symptoms that may be present in various forms of disease conditions. It is of interest that the German statistics show this condition to be much more frequent in women than in men. The subject is dealt with under the following divisions: origin, symptoms, differential diagnosis, complications, diagnosis, and treatment. This volume is a very valuable one, giving as it does so thoroughly a review of such important conditions.

The appearance of these two large volumes, devoted primarily to the treatment of nervous and mental diseases, will be most cordially welcomed by all students of neurology, but by all who have the welfare of the human race at heart since the work deals not only with the treatment of the individual forms of nervous and mental disorders but presents the viewpoint of the mental agencies at work in the production of these diseases and the means of preventing and controlling them. Much space is devoted to the social relations of
man, and emphasis laid upon psychic problems of life. "The present work—sets forth doctrines of nervous and mental hygiene, reconstructive factors in social organization as applied to human ills, and endeavors to present a broad front to the pessimistic nihilism in therapeutics that has been too long current in these fields." The first volume contains contributions by many different authors, and is devoted largely to a consideration of sociological problems, such as eugenics and heredity in nervous and mental diseases, by White; sexual problems, the nervous and mental relationship of tabes dorsalis, etc., by Erle; the educational treatment of the feebleminded, by Goddard; delinquency and crime, by Healy; immigration and the mixture of races, by Salmon, as well as to the treatment of the neuroses and psychoses. Freud's methods of treatment in the neuroses and psychoneuroses is admirably presented by Ernest Jones. The second volume contains seventeen chapters which deal with few exceptions with organic diseases of the nervous system, and which represent the contributions of authors of recognized prominence. Without exaggeration it may be stated that the present work is unique in being a complete exposition of the present day status of the prophylaxis and treatment of disorders of the nervous system.

While not posing as a textbook, this book presents in the form of clinical lectures carefully analyzed material concerning the most common and important forms of mental disease. The personality of Kraepelin is prominent throughout the work, the greatest value of which lies in the elucidation of the author's methods of investigation and analysis rather than in the presentation of scientific records.

The nineteenth edition, called in the title page the New American Edition of Gray's Anatomy, prepared by Dr. Edward Anthony Spitzka, has appeared a few weeks ago. There have been quite a number of changes made, especially under the heading of Applied Anatomy. Many important medical and surgical considerations have been added, but the greatest change, which will be welcomed by every student of anatomy, has been the addition of the Basle nomenclature (which is used in Italiens). The number of illustrations has been increased from 1,208 to 1,255, while the number of pages has been hardly altered at all. The proof reading has been very carefully done and many errors of form and of typography have been corrected. We congratulate the publishers as well as the editor upon the appearance of an edition of a book which will always remain dear to the heart of every medical student.

Malaria. Etiology, Pathology, Diagnosis, Prophylaxis, and Treatment. By Graham E. Henson, M.D., Member of the American Society of Tropical Medicine, Medical Reserve Corps, United States Army, etc. With an Introduction and Preface by Bishop M. D., Professor of Experimental Medicine, Medical Department, Tulane University, New Orleans. Twenty-seven Illustrations. St. Louis: C. V. Mosby Company, 1913. Pp. 190. (Price $2.50.)

At the present time there is probably no disease of greater importance to, at least, the southern portions of the United States than malaria. It is the disease, the eradication of which, probably permitted the completion of the Panama Canal. Hensin in his volume gives in most interesting form a very thorough presentation of this important subject. The chapter dealing with the general considerations reviews the widespread geographical distribution of this disease as well as the economic loss with which it is truly tremendous. In successive chapters the etiology, diagnosis, prophylaxis, and treatment are considered at length. Bass's method for the cultivation of malarial plasmodia is given fully. In regard to treatment the author uses a slight modification of Manson's method. He gives five grains of quinine sulphate every four hours during clinical manifestations; five grains three or four times a day for ten days or two weeks after the subsidence of symptoms; and after that ten grains in two or three doses every alternate day for at least a month. This publication is a very valuable addition on the subject of malaria and can be recommended highly.

Meetings of Local Medical Societies.

Monday, October 27th.—Medical Society of the County of New York.

Tuesday, October 28th.—New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Psychoanalytic Society; New York Dermatological Society; Metropolitan Medical Society of New York; New York Medical Union; New York Riverside Practitioners' Society; Valentine Mott Medical Society, New York; Washington Heights Medical Society, New York; Woman's Hospital Society of New York; Alumni Association of Seney Hospital, Brooklyn; Buffalo Academy of Medicine (Section in Pathology); Rome, N. Y., Medical Society.

Friday, October 31st.—Hospital Graduates' Club, Brooklyn; Audubon Medical Society, New York.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 15, 1913:

Surgeon, J. F. W. McEuen, who was detailed to proceed to Asheville, N. C., for conference regarding the investigation of a remedy for tuberculosis. Lumsden, L. L., Surgeon. Directed to proceed to Cumberland, Md., to continue investigations of typhoid fever; also to Martin, W. O., Va., for similar investigations and to deliver an address on the present status of typhoid fever in that section. McMullen, John, Surgeon. Directed to rejoin station at Baltimore, Md., stopping at the Bureau of Medicine and Surgery, Washington, D. C., en route.

Boards Convened:

Board of medical officers convened to meet at the Bureau, Monday, October 27, 1913, at 10 o'clock a.m., for the examination of Passed Assistant Surgeon Herman B. Parker, to determine his fitness for promotion to the grade of surgeon. Detail for the board: Surgeon W. G. Stimpson, chairman; Surgeon H. S. Cumming, member; Surgeon John McMullen, recorder.

Board of medical officers convened to meet at Honolulu, Hawaii, Monday, November 3, 1913, at 11 o'clock a.m., for the examination of Third Lieutenant K. A. Bothwell, United States Revenue Cutter Service, to determine his physical fitness for promotion. Detail for the board: Surgeon F. E. Trotter, chairman; Passed Assistant Surgeon M. D., Fauntleroy, recorder.

Board of medical officers convened, at the request of the Commissioner General of Immigration, to meet at the call of the chairman, for the reexamination of Elias Hoffman, an alien child now under treatment in the Garfield Hospital in Washington, D. C. Detail for the board: Surgeon Joseph Goldberger, chairman; Surgeon J. W. Scheeschwsky, member; Surgeon B. S. Warren, recorder.
United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending October 18, 1913:

De Witt, Wallace, Major, Medical Corps. Relieved from duty in the Hawaiian Department, and upon arrival at Honolulu of the transport to sail from Manila on or about December 15, 1913, will proceed to San Francisco, Cal., and report for further orders. Duncan, Louis C., Captain, Medical Corps. Relieved from duty at Washington Barracks, D. C., effective on arrival of Captain Mark D. Weed, Medical Corps, and will proceed to Fort Bliss, Texas, for duty. Duncan, William A., Captain, Medical Corps. Granted leave of absence for one month. Eastman, W. R., Major, Medical Corps. Granted leave of absence for three months, from October 1, 1913. Freeman, H. L., First Lieutenant, Medical Reserve Corps. Granted leave of absence for three months, about January 1, 1914, with permission to apply for one month's extension. Gapon, Nelson, Captain, Medical Corps. Relieved from duty as attending surgeon, Boston, Mass., to take effect on arrival in that city of Lieutenant Colonel Henry A. Shaw, Medical Corps, in compliance with orders heretofore issued, and will then proceed to Fort Rober, Mass., for duty. Higginbotham, Horace E., Captain, Medical Corps. Granted leave of absence without pay for six months, effective on April 11, 1914. Moncrief, W. H., Captain, Medical Corps. Will report in person without delay to the commanding officer, Fort Myer, Va., for temporary duty. Parisaie, M. T., First Lieutenant, Medical Corps. Arrived in New York on October 8th, 1913, with leave of absence. Roberts, Ernest E., First Lieutenant, Medical Corps. Granted leave of absence for three months. Van Poole, Gideon McD., Major, Medical Corps. Relieved from duty at St. Louis, Mo., and on January 5, 1914, will take transport for Honolulu, H. T., for duty. Wilson, Elisha, First Lieutenant, Medical Reserve Corps. Relieved from treatment at the Letterman General Hospital, San Francisco, Cal., and will proceed to his home, on an expiration of leave of absence will stand relieved from active duty in the Medical Reserve Corps; granted leave of absence for three months and fourteen days, effective on arrival at his home. Wright, F. S., Captain, Medical Corps. Ordered to Fort Sill, Okla., for temporary duty.

**Births, Marriages, and Deaths.**

Married.

Butler—Dodd.—In Trenton, Tenn., on Wednesday, October 1st, Dr. Willis Pollard Butler, of Nashville, and Miss Annie Perry Dodd. Cunningham—Taylor.—In East Lake, Ala., on Saturday, October 4th, Dr. Russell M. Cunningham, of Ensley, and Miss Anne Taylor. Deppe—Halley.—In Baltimore, Md., on Saturday, September 27th, Dr. Albert P. Deppe and Miss Elizabeth Halley. Fishel—Hall.—In New York, Capt. Henry M. Fishel and Miss Cora Hall, on Saturday, October 1st, 1913, will proceed to Plattsburgh, N. Y., for temporary duty. Martin—McCurdy.—On Saturday, October 11th, Dr. Howard McCurdy and Miss Minnie E. Martin, New York, N. Y., on January 5, 1914, will take transport for Honolulu, H. T., for duty.

**Deaths.**

Harvey.—In Brein, Sunday, October 12th, Miss Lydia H. Harvey, aged seventy years. Harrod.—In Galatia, Ill., on October 12th, Dr. A. J. Harrod, aged seventy-two years. Hathaway.—In Cincin-

COMMON ERRORS IN THE DIAGNOSIS AND PROGNOSIS OF GALLSTONE DISEASE.
Illustrated by a Report on Twenty-seven Recent Operations.

By Benjamin T. Tilton, M.D., New York.

The great advances that have been made during the past few years in our knowledge of gallstones, and particularly of the changes they produce in the biliary system and in other organs, are largely due to the experience gained at the operating table. The end results seen at autopsy throw comparatively little light upon the sequence of events which have led to the fatal outcome. Operation, however, has revealed the local conditions of every stage of inflammation or obstruction, and has cleared up debated questions to a degree not possible by any other form of study. The surgeon has thus become the authority in regard to the manifold changes produced by the presence of gallstones, and is in a position to refute many of the theories and conclusions based on purely medical and post mortem investigations. In his studies the surgeon has, it is true, had great assistance from the clinical pathologist and, in fact, is often dependent upon the latter’s findings, for the exact diagnosis and the indications for surgical treatment. It should be frankly admitted by the general practitioner that the surgeon has come to possess superior practical knowledge of gallstone disease, owing to his familiarity with the pathological findings in the living. Consequently a case of supposed gallstones should have the combined advice of the internist and surgeon just as is the general custom in cases of appendicitis. This will be not only of the greatest value to the patient, but will be mutually advantageous to the internist and surgeon by an interchange of views very differently acquired.

The physician would profit greatly by more frequently visiting the operating room, and seeing the actual local conditions on the living. The knowledge here obtained would be a useful supplement, and would bring home forcibly the various stages of the pathology, the simplicity of procedure in early cases, the difficulties and dangers in complicated cases, and the correlation between disease of the gallbladder and that of the adjacent organs. It has seemed to the writer that there are still current among the profession certain ideas regarding gallstones, which are not in keeping with the actual facts as demonstrated by operative experience. As a result of these incorrect views, mistakes in diagnosis are inevitable, and patients are treated over long periods for other troubles, and valuable time thus lost.

ASSOCIATION OF JAUNDICE WITH GALLSTONES.

It is remarkable how strongly rooted the impression is in the profession that gallstones are usually associated with jaundice. As a matter of fact this combination is the exception and has been estimated to occur in as few as twenty per cent. of the cases. To exclude cholelithiasis then because there is no sign or history of icterus is manifestly absurd. It is possible for the patient to have numberless attacks of pain and very marked changes in the gallbladder without a sign of jaundice, simply because there has been no mechanical or inflammatory arrest of the flow of bile through the common duct. Even though stones reach the common duct and remain there, jaundice may be entirely absent. I recently operated in a case in which I found no less than twelve good sized stones in the common and hepatic ducts, and no jaundice. The most common cause for jaundice in connection with gallstones is not mechanical obstruction by a stone, but inflammatory swelling of the mucous membrane of the hepatic and common ducts. This jaundice is not infrequent, when there are stones in the common duct, and then it is intermittent. The theory that this intermittent jaundice was due to the ball-valve action of the stone is probably not correct. When the stone has not gotten beyond the gallbladder or cystic duct, jaundice from mechanical obstruction is hardly conceivable, except in the case of a very large, distended gallbladder which might press upon the common duct or cause angulation of the same or, in the case of adhesions constricting the duct. Exceptionally the stone in this situation may be the cause of jaundice, by causing first a cholecystitis which may spread to the hepatic and common ducts, producing inflammatory thickening of the mucous membrane with obstruction. A still further cause for jaundice is the extension of the inflammation to the head of the pancreas, with chronic thickening of the same, and secondary obstruction of the common duct. This may occur in the case of stones in the gallbladder as well as of those in the common duct. The stone thus plays in itself a small rôle in the direct causation of jaundice, and usually acts indirectly by causing inflammation which, by obstruction, may result in jaun-

Copyright, 1913, by A. R. Elliott Publishing Company.
disease. In very rare cases a stone may actually occlude the ampulla of Vater, in which case the jaundice would be due to the mechanical action of the stone in this location. If not dislodged by nature, or by operation, such a stone completely arrests the flow of bile into the intestine, and a fatal cholecystitis results. Such a case is most exceptional and should not be taken as a type of common duct obstruction. After long persistence of inflammatory changes in and about the gallbladder and ducts, jaundice may result from obstruction of the common or hepatic duct, by adhesions compressing the same, or by stricture due to healed ulceration. These again

are merely secondary results of stones and may persist after removal of the same.

INCORRECT INTERPRETATION OF SYMPTOMS.

Another common belief held is that the symptoms caused by gallstones are always directly referable to the liver and biliary ducts. This mistaken idea has probably been the cause of most errors in diagnosis. The classic symptoms that have long been ascribed to cholecystitis are unfortunately the exception. We are now realizing that other organs, particularly the stomach, give the first evidence of gallstones, and that it may not be until months or years later that the symptoms point directly to the liver and bile ducts.

Patients with epigastric pain and stomach symptoms are constantly being treated for "indigestion," while the real trouble—gallstones—is entirely overlooked. Stomach clinics are visited by patients with gallstones who are religiously treated by stomach lavage, antacids, gastric sedatives, etc., without relief.

I recently operated upon a woman who for ten years had been under the constant care of a prominent specialist for stomach trouble. Operation revealed a gallbladder distended with large stones, secondary pancreatic carcinoma, and resulting common duct obstruction with jaundice. It was this long delayed symptom of jaundice which first suggested to the physician the possibility of gallstones. It is true that many cases begin with typical symptoms which point directly to the biliary system, and which are extremely easy to diagnose. Hence

physicians have come to associate a certain group of symptoms with gallstones, and the absence of these symptoms leads them into the error of excluding cholecystitis from the diagnosis. This seems only a natural mistake, but at the present time is not an excusable one. Continued attacks of epigastric pain, distention, and vomiting, unrelieved by medical measures, in an individual at the gallstone age, especially a woman who has had numerous children, and in the absence of definite changes in the chemistry of the stomach analysis, should make the physician suspect gallstones even though there is no enlargement or tenderness of the gallbladder, pain in the scapular region, or jaundice. The following case illustrates in a typical way this puzzling group of symptoms.

Case. A woman of forty years had been treated for five years by different physicians for acute attacks of stomach disturbance, which were very severe and accompanied by excessive vomiting. The attacks were not asso-

1 optimized recovery, D. died.

2 Died of exhaustion in 7 weeks.
associated with much pain. A few days rest in bed and careful diet brought relief. The stomach analysis was normal and the x-ray negative. Nothing suggested cholelithiasis. No jaundice, scapular pain, nor tenderness over the gallbladder. On account of recurrence of the attacks and persistent loss of weight an exploratory laparotomy was deemed justifiable. The stomach was found to be normal, but the gallbladder contained between two and three hundred faceted stones of medium size. The gallbladder was not the seat of inflammation or obstruction. Removal of the stones and drainage of the gallbladder resulted in a cure.

TENDENCY TO UNDERESTIMATE THE SERIOUS CONSEQUENCES OF GALLSTONES.

It is evident that a failure to recognize the real nature of these cases, over a long period of time, may lead to serious changes in the gallbladder, bile ducts, pancreas, and other organs. As a consequence a simple lesion becomes a complicated one and the patient runs the risk of a sudden attack of acute cholecystitis, obstruction of the common duct, infections cholangitis, or of the gradual development of painful adhesions about the gallbladder and ducts, pyloric obstruction, chronic pancreatitis, cancer of the gallbladder, and other lesions resulting from the continued presence of stones. We can no longer regard gallstones as a menace only to the comfort of the individual. They are a real menace to life as well. The physician too often shares the view of the patient that relief from the agonizing pain is equivalent to a cure. The surgeon knows too well that stones which have once begun to cause marked symptoms will continue to do so on account of the anatomical changes that were associated with the first attack, and which will progress to still more important alterations in the biliary system. A gallbladder which has once been the seat of acute inflammation does not spontaneously return to the normal again, any more than the inflamed appendix does. Hence the repetition of the attacks until finally very serious changes occur, not confined to the gallbladder, but affecting the ducts, the liver, the pancreas, the stomach, etc.

These changes mean, if unrelied, danger to the life of the individual from sepsis, perforative peritonitis, cholelithiasis, intestinal obstruction, pyloric obstruction, cancer (especially of the gallbladder), myocarditis, chronic nephritis, etc. It is important to recognize the presence of gallstones the moment that they cause their first symptoms, and apply the appropriate treatment, and not permit them to continue their local changes because of a wrong diagnosis or a disregard of their seriousness. It is no mere theory that the continued irritation from gallstones produces cancer of the gallbladder. Since the great increase in the number of operations on the biliary passages, gallbladder cancer has been found to be by no means a rare condition. It has been estimated that it is preceded by gallstones in 95 per cent. of the cases. Furthermore chronic pancreatitis, which Mayo Robson found in sixty per cent. of his cases of common duct stones, is undoubtedly a predisposing factor in the development of cancer in the head of the pancreas. The serious aspects of gallstone disease result, in the great majority of cases, from delay and, hence, the mortality rate increases with the duration of the disease. The same is true of the results of operative interference. Early operation in the absence of serious complications means a low mortality, whereas late operation after the development of jaundice, adhesions, or cancer is attended with danger, and requires special skill and judgment to insure a good result. In the case of cancer of the gallbladder the outlook is almost hopeless. During the past year I have operated in twenty-seven cases of gallbladder disease, stones being present in all but three cases. I have taken pains to have noted in the histories the facts relating to the three points under consideration, 1, as to the occurrence of jaundice; 2, as to the presence, particularly at the outset, of other symptoms than those directly referable to the biliary system; 3, as to the occurrence of serious complications from gallstones that are allowed to remain. From the compiled cases it will be seen that jaundice was present four times in twenty-seven cases, or a little under fifteen per cent. There was a history of stomach symptoms in fifteen cases, or fifty-eight per cent. There were present at operation serious complications in eighteen cases, or sixty-six per cent. As regards the choice of operative procedure, cholecystostomy was performed fifteen times, cholecystectomy eleven times, and cholecystectomy three times. The number of deaths in cases free from serious complications (ten in number) was nil.

Of cases associated with serious complications (eighteen patients) three died. Of these one had primary carcinoma of the gallbladder (Case III), a second carcinoma of the pancreas with secondary nodules in the liver (Case XXVI), and a third advanced myocarditis, nephritis, and chronic hepatitis with jaundice (Case XXVII). These three fatalities occurred in individuals with gallstones who had been for years under treatment (one for ten years), and were not advised to have an operation until the grave complications had shown the futility of further medical treatment. The blame for these deaths should clearly be placed upon the first medical advisers, who erred either in the diagnosis or prognosis of gallstones, and not upon surgery which cannot hope to save patients in whom cancer of the biliary apparatus has been allowed to develop, or advanced degenerative disease of the liver, heart, and kidneys.

SPECIAL TECHNIC IN PALPATION.

By L. NAPOLEON BOSTON, A.M., M.D.,

Philadelphia,

Professor of Physical Diagnosis, Medical College of Philadelphia; Physician to the Philadelphia General Hospital; Pathologist to the Frankford Hospital.

It is the purpose of this paper to describe by text and show by illustrations, practical methods not generally in use.

The correct employment of palpation for the recognition of disease of the lung is believed by the writer, to be among the most valuable of physical methods. Whenever it is desirable that the exact extension of a pulmonary lesion be ascertained, palpation serves this purpose equally well, and at times more advantageously than any other physical method.

The accompanying illustrations are taken from cases in the wards of the Philadelphia General Hospital, and the findings resulting from the employ-
similarly imperfect record is obtained when abnormal fremitus is conveyed only to the third finger (Fig. 2), and here again the mental record is such as to lead the operator to believe that the entire surface palpated by all four fingers gives increased fremitus.

After it has been found that a certain portion of the chest gives increased fremitus, the next step in the examination is to determine the exact extension of the lesion accountable for such fremitus. This is done by placing one index finger some distance beyond the area where increased fremitus is produced, and traveling slowly with this finger toward the lesion. Whenever the palpating finger reaches a point where the fremitus is increased, this point should be designated by the pen. This same procedure should be employed to ascertain the boundary of the area of abnormal fremitus on all sides. After the area of increased fremitus has thus been roughly outlined, place one index finger immediately inside the limiting line, and upon the area where fremitus is increased (Fig. 1), and at the same time place the index finger of the other hand but a short distance beyond the line. In this last position carry the two fingers in a step-like manner along the line designating the approximate limitation of the area of increased fremitus. The finger palpating over the lesion will be found to elicit increased vocal tactile fremitus, while the other index finger palpating immediately beyond the lesion detects a lesser degree and in many instances normal fremitus. This method will be

---

A

---

ment of palpation have in each and every instance been confirmed by further physical study, the x ray, and at times by autopsy. In comparing the two halves of the chest it is all important that we employ corresponding areas for study. One must ever keep in mind that pleural adhesions may conduct abnormal vibrations to the chest wall. In order to eliminate the misleading element of increased fremitus resulting from pleural or pericardial adhesions, a useful practice is to employ only the index fingers of the two hands. (Fig. 1.) The tip of the index finger receives sensations from an area of the chest approximately the size of a dime. It will be found that, but little additional time is necessary to traverse the entire chest wall in this manner, and the results obtained are by far more valuable than those gained through the application of two or more fingers of the same hand to the surface of the chest. Again, the index finger is decidedly more sensitive than are the other fingers. The index, the second, and half of the third fingers are supplied by the median nerve, while the other half of the third, and the fourth fingers are supplied by the ulnar nerve. (Fig. 2.) Where all the fingers are placed upon the chest, sensations conveyed to the first, second, and third fingers give the operator the mental impression that the entire area upon which these three fingers rest is responsible for the increased fremitus present. Should the four fingers be separated at some distance, any unusual vibration conveyed to any of the fingers is liable to confuse the operator, a feature especially true when the abnormal sensations are received only by the fourth finger and by the index finger (the evidence being that the entire surface palpated is responsible, while the index and fourth finger may be the only tracts to receive abnormal fremitus). (Fig. 3.)

---

Fig. 1.—Determining the exact boundary of an area of pulmonary consolidation through the degree of vocal tactile fremitus. The left index finger recorded far more fremitus than did the right. The tip of the index finger receives sensations from an area of the chest approximately the size of a dime.
found of special service where the lesion and consequently the area of increased fremitus are irregular in outline.

In palpating for the detection of expansible pulsation, the position of the operator's fingers must vary, depending upon the location of the aneurysm. Apply the four fingers and the thumb to the pulsating mass in such a way that they more or less completely surround it. (Fig. 4.) The sensation of true expansion with each heart beat is conveyed to the operator's hand most distinctly, when the above described technic is followed. This method has been employed by the writer in distinguishing between aneurysm of the carotid regions, and pulsations due to other causes. In studying aneurysm of the abdominal aorta and pulsations conveyed through some solid viscus or growth, this technic has proved of inestimable value.

To establish the outer margin or area over which pulsation is detected employ the method described under palpation of the lung. (Fig. 1.) After the boundary of the pulsating area has been established by careful palpation, adjust the four fingers' tips and the thumb along the margin of the pulsating mass, and gradually cause the fingers to approach the centre of the pulsating surface until a heaving or expanding sensation is apparent at each finger. (Fig. 4.)

In palpating for the edge of the liver, a procedure which I have seldom seen employed, and which in my hands serves as one of real worth is as follows: While the patient is standing place the fingers of the palpating hand at approximately the lower border of the liver; and direct the patient to raise the heel of the right foot so that he stands with but a small portion of his weight upon the right toe. This position (Fig. 5) will be found to

![Fig. 3.-Palpation of two small areas where fremitus is increased.](image1)

![Fig. 4.—Method of detecting expanding pulsation of the abdomen.](image2) The patient displayed extreme pulsation of this area, which was shown by autopsy to be an aneurysm of the abdominal aorta.

![Fig. 5.—Here the patient rests the right foot upon a small box, which gives identically the same result as standing with but a small portion of his weight on the right toe.](image3)
relax the abdominal wall over the right hemisphere. This method serves of equal value in palpation of the right kidney, and of the appendicular and pelvic regions. The same procedure is equally well adapted for the study of the left abdominal hemisphere.

During the past six years it has been the writer's custom to employ the technic hereafter described for the purpose of determining the degree of tension over various portions of the abdominal surface. It will be found that in normal subjects, when the patient is resting upon his back with the thighs flexed, there is a slight increase in tension immediately below the right costal margin (hepatic tension). This area when compared with the same area in the left superior abdominal quadrant, offers slightly more resistance to the palpating finger. Comparing the two sides of the abdomen, one or two inches above the level of the umbilicus, the same degree of resistance is offered to the palpating fingers. There is no appreciable difference in the resistance of the two sides of the abdomen below the umbilicus during health. (Fig. 6.) This method for palpating the two halves of the abdomen simultaneously, as shown by the accompanying illustration, is to begin immediately above Poupart's ligaments, ascending in lines drawn from the center of Poupart's ligaments to the costal border. Continue by comparing the two halves of the abdomen at equal levels ascending to the margin of the ribs. One may also palpate the abdomen, employing the same scheme and ascending from the inferior abdominal region to the costal margin, following lines approximately two inches to the right and the same distance to the left of the line previously mentioned. (Fig. 6.) Through this method of palpation it is possible to elicit one of the most delicate signs of new growths of the abdomen. Enlargement of the liver, spleen, kidneys, uterine, ovarian, cystic growths, and fecal impaction are all placarded by a localized increase in tension of the abdominal wall over the site of the lesion. Pro-lapse of any viscus causes a lessened resistance to the finger when palpating over its normal position; and increased tension is detected immediately over the present position of such migrating viscera. Localized inflammatory processes involving the abdomen are accompanied by undue tension over a limited portion of the abdomen, and this is exemplified in acute appendicitis, pyosalpinx, gastric cancer, and conditions accompanied by localized peritonitis. Posture may materially alter the degree of abdominal tension, therefore it is preferable to palpate while the patient is resting upon his back, on his right side, on his left side, and when standing.

**INDUCED PNEUMOTHORAX,**

*Preliminary Report.*

BY H. SCHWATT, M.D.,
Edgewater, Colorado,
Superintendent of the Sanatorium of the Jewish Consumptives' Relief Society.

The treatment of advanced pulmonary tuberculosis by means of induced pneumothorax is gaining wider and wider recognition and the literature on artificial pneumothorax has, within the past few years, become voluminous. It is, however, to be regretted, in a procedure which constitutes, perhaps, the greatest advance in the treatment of cases previously considered hopelessly advanced, that there exists so much of radical difference of opinion as regards nearly every important phase of the subject. It is the conflicting opinions of clinicians with the greatest experience in this field in regard to the indications, and the numerous modifications of apparatus and technic, which deter us from undertaking this method of treatment, which in numerous cases has been productive of brilliant and lasting results and that irrespective of any particular form of technic employed.

The value of artificial pneumothorax must eventually be decided upon the results obtained in a large number of cases so treated, and in order to draw definite conclusions from reports they must emphasize certain definite and important points. In many cases the most vital data relating to the case are left to the imagination of the reader and information is omitted which is absolutely essential in establishing a correct opinion regarding the value of the treatment, or whether the ill results described have been due directly or indirectly to the collapse of the diseased lung.

It is not my purpose to cover in this preliminary report the entire field of the theory and practice of
artificial pneumothorax. It is merely intended to call attention to:

First, the technic employed.

Second, the method of presenting case histories and of keeping uniform records of cases treated by means of induced pneumothorax.

TECHNIC.

The Forlanini, or the so called puncture method, has been employed in the cases reported.

The injection apparatus and the needles employed are not described in detail. (Fig. 1.) All apparatus in use are based upon the same principle and are modifications of those originated by Forlanini, Brauer, Saugman, von Muralt, and Kornemann.

The cylindrical jars seen in the illustration were added to the original apparatus and are for the purpose of using oxygen gas if desired. The needles are graduated at ten millimetres' distances from the point so that the operator may easily determine at what depth it enters the free pleural space, and as a guide for subsequent operations. The needle is provided with a sliding circlet of a definite length (ten millimetres), and may be fixed at any desired point by means of a set screw to prevent the needle from slipping. (Fig. 2.)

All instruments employed are to be sterilized as for a major operation. The patient is given an injection of one eighth grain of morphine. The side of the chest to be operated on is then thoroughly cleansed with tincture of green soap followed by alcohol. The operator, whose hands are sterile, then injects at the selected site about one cubic centimetre of a solution containing novocaine, grain one third, and epi- nephrin, grain 1/200. This injection is made by inserting the needle under the skin in all direc-

tions and down to the pleura. The site of the puncture is then painted with tincture of iodine, and after waiting a few minutes to allow the local anesthetic to act, an incision down to the pleura is made with a sharp narrow scalpel. The latter is provided with a guard. Occasionally there may be slight bleeding at the point of incision, and it is advisable to wait until this ceases before inserting the pneumothorax needle so as not to aspirate blood into its lumen. The needle is first tested by allowing some of the gas to flow through it into alcohol. The threeway stop cock of the apparatus is then turned in such a manner that the needle is connected with the manometer only. Through the incision the needle is slowly inserted under the guidance of the manometer until respiratory oscillations set in and a reading is obtained which indicates that the point of the needle has entered a free pleural space. The circlet is then fixed by means of the set screw and the injection of gas may be proceeded with.

The author uses oxygen gas for the first, and frequently for the second injection. Under no circumstances is any gas allowed to flow in before there is a conclusive indication that the point of the needle is in a free pleural space. What methods have we for determining that such is actually the case? Without entering into a discussion of the manometer readings obtained under various conditions, suffice it to say that a distinctly negative reading with both inspiration and expiration, and a greater negative reading with inspiration than with expiration, are practically conclusive evidence that the needle has entered the pleural cavity. Occasionally we find a distinct negative reading with inspiration which becomes slightly positive on expiration. This may be due to forcible expiratory efforts of the patient as a result of excitement. As a further indication the patient is instructed to take a moderately deep inspiration and to hold his breath at the end of it. If the manometer then remains stationary at a negative reading, one may be certain that the point of the needle has reached a free pleural space. Should the point of the needle be in the lung tissue, the column will drop from negative to zero while the patient is holding his breath. The insertion of the needle into the lung tissue is in itself devoid of any danger.

The patient is placed in a position which allows of the widest separation of the ribs, and so that the point of injection is the highest in relation to the chest wall.

It is the author's practice to inject the gas in small quantities especially at the first operation. No more than from fifty to one hundred cubic centimetres of gas are injected without taking a manometer read-

---

Fig. 1.—Author's injection apparatus.

Fig. 2.—Needle and scalpel.
it a practice for his patients to assume the erect posture gradually, especially in cases where the mediastinum has been displaced to any marked degree. This procedure obviates the occurrence of dizziness and nausea which frequently follow the operation. Where the patient is subject to a cough, a small pill bottle is secured over the puncture by means of adhesive plaster for about twenty-four hours to avoid the occurrence of subcutaneous emphysema.

With careful technic the accidents and complications in induced pneumothorax are reduced to one — emphysema of the cellular tissue. This usually occurs as a result of the escape of gas during or after the operation due to coughing. It may be the result of injury of the lung tissue, in which case the emphysema may be considerably increased by respiratory movements and coughing. Occasionally the extent of the emphysema may appear alarming. It is, however, rarely a dangerous complication. If it is due to severe cough it is advisable to give a sedative for a few days. Further injections should not be given until the emphysema has completely disappeared.

METHODS OF PRESENTING CASE HISTORIES AND KEEPING RECORDS.

In undertaking to induce an artificial pneumothorax, many factors must be taken into consideration. The patient should be made acquainted with the seriousness of the treatment and should be impressed with the fact that the induction of an artificial pneumothorax is a major operation and subject to various accidents and complications. The most important questions to be considered as to whether or not the treatment should be undertaken are: 1. The duration of the disease. 2. The previous methods of treatment pursued and results obtained. 3. The general condition of the patient. 4. The physical findings. 5. The X-ray findings. 6. The complications, tuberculous and nontuberculous. 7. The economic factors.

![Image 1](https://example.com/image1.png)

**Fig. 3.**—Case I, showing partial collapse of left lung.

![Image 2](https://example.com/image2.png)

**Fig. 4.**—Case II, showing collapse of right lung.
All these points should be embodied in reports of cases treated by artificial pneumothorax.

The indications for the performance of an induced pneumothorax have been set forth by various authors within varying limits. The writer has confined himself to unilateral cases or cases with inactive involvement of the other lung. In regard to the firmness or extent of the pleural adhesions, it may be said that neither by physical examination nor by X-ray findings can it be positively determined beforehand, whether it will be possible to produce an artificial pneumothorax, or the extent to which the lung may be collapsed.

The author has devised a blank which is used to record each individual operation. The other side of the blank serves for a clinical report since the last injection in regard to cough, expectoration, appetite, digestion, bowels, sleep, night sweats, kidney symptoms, dyspnea, pain, chills, temperature, pulse, etc.

Before each injection an examination of the lungs is made with special reference to the presence of fluid. Particular stress is laid on the examination of the healthy lung. The position of the mediastinum is noted before and after each operation.

REPORT OF CASES.

Case I. R. S., male, aged twenty-six years. Admitted March 18, 1913. Duration of disease, fifteen months. Previous treatment, medical. He had lost twelve pounds since July, 1912. He came to Denver from St. Stephens Bay, N. B., Canada, in December, 1912. Two weeks before admission he had a moderate hemorrhage. On admission he complained of severe cough at night, dyspnea on slight exertion, occasional chills, moderate degree of fever, and pains in the left side. The patient was pale and presented an unhealthy and hectic appearance.

Physical examination: Extensive infiltration of the left lung and harsh breathing, with slightly prolonged expiration at the right apex. No rales on the right side. Crackling rales over the entire left lung. The patient was confined to bed more or less until the pneumothorax treatment was undertaken, with his temperature rising frequently to 106° F. and 100.8° F. His pulse ranged from 78 to 104; he had a cough, which was especially severe at night, and an expectoration of from three to four ounces in twenty-four hours. Tubercle bacilli found in sputum. By April 1st the patient had lost five pounds. He felt that he was losing ground and asked that a collapse of the left lung be undertaken.

An X-ray plate confirmed the physical findings of the left lung, but also showed some infiltration of the right lung which, on account of the absence of physical signs, was considered inactive. The first injection of nitrogen gas was given April 26th. The needle was introduced in the seventh interspace in the midaxillary line. During the following injections, and after the first injection the patient suffered a rather alarming degree of shock with rapid and weak pulse and nausea, followed by vomiting after the needle was withdrawn.

A total of 5,000 c.c. of nitrogen gas in eleven injections.

Three X-ray plates had been taken since the injections were begun, the last on July 24th, showing a very satisfactory degree of collapse. The mediastinum was somewhat displaced, about three centimetres to the right. The only complications during the course of treatment had been dizziness, nausea, and vomiting following the eighth injection. Physical examination of the right lung showed no change. (Fig. 3.)

The improvement in this case had so far been very satisfactory. There had been no rise of temperature above normal. The expectoration had diminished to about half an ounce, and on many days the patient had had none. The sputum had been repeatedly examined and was first found to be negative on May 12th. Repeated examina-

by the ordinary and antiformin methods failed to reveal bacilli. Patient had entirely lost his cough. The general condition was splendid. There had been a gain of ten pounds since the treatment was begun. There was no dyspnea. Patient was anxious to leave the sanatorium to take up his work as shoemaker.

Case II. S. L., male, aged twenty-nine years. Admitted March 26, 1913. Duration of disease, according to patient, nine months. Previous treatment, medical. Came to Denver six weeks before admission. Had lost sixteen pounds since the onset of the disease. He never had any hemoptysis. On admission he complained of moderate cough at night and an expectoration of about one ounce in twenty-four hours. Tubercle bacilli found in sputum. He was a well nourished individual of medium build, but of a somewhat cyanotic appearance. The physical examination was confirmed by an X-ray plate showing an extensive infiltration of the right lung. Moist rales throughout. Left lung: Moderate involvement at base and in lower axilla. A few crackling rales over these areas which largely disappeared after coughing.

In this case a pneumothorax was induced not for the relief of any particular symptoms, but at the request of the patient, who desired to take this means of regaining his health and to return to earning capacity.

SCHWATT: INDUCED PNEUMOTHORAX.

No complications during the treatments. Three x ray plates taken, the last on July 24th, showed a satisfactory degree of collapse. No change in the left lung. Sputum negative on July 12th, and on subsequent examinations, by the ordinary and antitoxin methods. No cough nor expectoration. Gain of weight, three pounds. No subjective evidences of disease. (Fig. 4.)

Case III. B. L., female, aged twenty-five years. Admitted August 7, 1912. Duration of disease, six months (?) . Previous treatment, medical. Came to Denver six weeks before admission. Symptoms on admission: Severe cough with an expectoration of four ounces in twenty-four hours; tubercle bacilli found in sputum; general condition unfavorable; weight, eighty-five pounds. From day of admission the patient had practically been completely bedridden with the following symptoms:

Temperature of a pronounced hectic type ranging from 96° F. in the morning to 101° F. in the afternoon, and at no time normal. Pulse ranged from 88 to 130. Night sweats, chills, gastric disturbances, and severe cough were present. The general condition of the patient being very unfavorable, she requested that a pneumothorax be induced.

Lung condition: Extensive involvement and fibrosis of the right lung with a large cavity at the apex and amorphous breathing extending to the third rib; also an infiltration of the left apex with a few rales on expiratory cough. There was harsh breathing over the entire left lung. An x ray plate confirmed the findings in the right lung and showed extensive infiltration of the left lung. On account of this it was explained to the patient that, if the treatment were undertaken, it would be done simply as a last resort. In spite of this, the patient requested to have it done. The following injections had been given to date, the needle being introduced through the fifth interspace in the midaxillary line:

June 11th. . . . 300 c. c. oxygen  July 2d. . . . 400 c. c. nitrogen
June 14th. . . . 250 c. c. nitrogen  July 8th. . . . 350 c. c. nitrogen
June 18th. . . . 300 c. c. nitrogen  July 11th. . . . 300 c. c. nitrogen
June 21st. . . . 250 c. c. nitrogen  July 15th. . . . 250 c. c. nitrogen
June 28th. . . . 300 c. c. nitrogen  July 20th. . . . 300 c. c. nitrogen

Physical examination now showed an extensive pneumothorax, confirmed by an x ray plate taken July 24th. No change in the findings of the left lung. Effect on symp-

toms: There had been a decided drop in the temperature, particularly since the sixth injection. (Fig. 5). Expectoration had decreased from three ounces to about one half ounce in twenty-four hours. The cough was very slight. There were no night sweats. The appetite was good, and the bowels regular. The improvement in the general condition of the patient was pronounced; she was then up and about the greater part of the day. (Fig. 6.)

Case IV. S. S., male, aged forty-two years. Admitted February 18, 1913. Duration of the disease, one and one half years. Onset with slight hemorrhage. In November, 1912, he had a profuse hemorrhage. He had an hemoptysis in December, 1912, and in January, 1913. He lost fourteen pounds since the onset. On admission he complained of severe cough with an expectoration of two ounces in twenty-four hours. Tubercle bacilli found in sputum. He had some digestive disturbances. His temperature was subnormal though rising occasionally to 100° F. His pulse ranged from eighty-eight to ninety-six. On March 22d the patient had a slight hemorrhage and raised bloody sputum until April 11th. Hemoptysis on May 3d and from May 31st to June 2d. Hemorrhage, ten ounces, on June 3d; hemoptysis to June 10th. Hemorrhage, eight ounces, on June 11th; hemoptysis until June 21st.

Physical examination showed extensive involvement of the right lung with cavity formation and crackling rales throughout. In the left lung there were moderately numerous rales up to the second rib. At the request of the patient an artificial pneumothorax was attempted on June 24th. It was not possible to have an x ray picture taken, the patient being bedridden.

The needle was inserted in the fifth interspace in the anterior axillary line, to the depth of thirty millimetres; no reading of the manometer obtained. The needle was reinserted at a little distance from the first puncture and, at a depth of sixteen millimetres a typical lung reading was obtained. The patient had a severe attack of coughing and before the needle was withdrawn an extensive emphysema developed. Within a few hours this extended to the other side of the chest, and up to the clavicles and to the abdomen. By July 2d the emphysema had disappeared. On July 2d the needle was introduced in the fourth interspace in the anterior axillary line and a free pleural space found. Two hundred and fifty cubic centimetres of oxygen were injected. On July 8th the reading was so indefinite on account of an attack of cough that.
after injecting twenty c. c. of oxygen the needle was withdrawn.

The following injections were subsequently given:

July 15th...115 c. c. oxygen  
July 20th...300 c. c. oxygen  
July 16th...400 c. c. oxygen  
July 23d...400 c. c. oxygen

An x ray plate taken July 24th showed a small area of collapse. The under portion of the lung was dense, apparently firmly adherent, and it was doubtful whether it would be possible to obtain a collapse. The injections were to be continued. There had been a marked diminution in the cough. (Fig. 7.)

Case V. A. N., male, aged eighteen years. Admitted February 27, 1913. Duration of disease, four months (?). Previous treatment, medical. Came to Denver six weeks before admission. On admission complained of moderate cough and an expectoration of about one ounce in twenty-four hours. General condition, poor. He had some gastric disturbances. His temperature was subnormal, but occasionally rose to 99.6° F. His pulse was about 100. Tubercle bacilli found in sputum. The patient was steadily losing weight, which was 126½ pounds on March 15th, and 116 pounds on July 1st. Physical examination showed extensive involvement of the right lung, with moist rales throughout. Left lung: Some rales below clavicle to third rib, and harsh breathing posteriorly in the suprascapular area. X ray plates confirmed findings in right lung, but showed more extensive infiltration of left lung than was found on physical examination. On account of the rapid loss of weight and generally unfavorable condition of the patient it was decided to attempt to collapse the right lung. The following injections had been given, the needle being introduced through the sixth interspace, anterior axillary line. After the first injection the patient suffered a marked degree of shock:

July 8th...200 c. c. oxygen  
July 11th...300 c. c. oxygen  
July 15th...400 c. c. nitrogen

An x ray plate taken July 24th showed a favorable degree of collapse of the upper and lower lobes. The middle lobe appeared to be held by adhesions. There had been a marked diminution in the cough and in the amount of the expectoration. (Fig. 8.)

In two cases we declined to undertake the collapse of the more diseased side on account of the more extensive involvement of the other side, as shown by the x ray plate, than was supposed to be present on physical findings. In one case one attempt was made, and further attempts given up, it being unlikely that a free pleural space would be found. In one case ten, in another seven, in another two, and in one three attempts were made without success. In several of these cases the Brauer method will probably be tried. In one case treatment was begun and interrupted as a result of an hemoptysis followed by aspiration pneumonía. In this case treatment will be continued. A collapse is being attempted in a case of abscess of the lung with unfavorable results so far.

The writer desires to thank Doctor Beggs, Doctor Taussig, and Dr. John Ostro for their assistance in giving the treatments.

THE TOXICITY OF COAL TAR PRODUCTS.

By G. Howard White, Jr., A. B., M. D., Baltimore.

In view of the recent government report by Hale describing a method for the determination of the toxicity of coal tar disinfectants, it does not seem out of place to call attention briefly to a fact which is of importance in this connection.

The method mentioned above employs mice as the subjects, and the drug is injected hypodermically in increasing doses until the minimal lethal dose is reached. The minimal lethal dose of phenol is used as a basis of comparison, and this figure divided by the minimal lethal dose of any particular disinfectant gives a factor which is termed the "toxicity coefficient" of the disinfectant in question.

In toxicity work the commonly accepted methods for the introduction of drugs are the hypodermic, the intraperitoneal, the intravenous, and the intragastric. On first thought it would appear that any one of the four methods would give practically identical findings where merely comparative results were desired between drugs of the same pharmacological group. Such, however, is not the case.

In 1907 Weyl reported an extensive series of experiments in which he introduced cresol, quinolinol, and other preparations into rabbits by the hypodermic, intraperitoneal, and intragastric methods with widely divergent results.

In a series of experiments carried out by the writer using rabbits and the intragastric route for the determination of the minimal lethal dose of phenol and of one of the modern coal tar disinfectants, a toxicity coefficient was obtained which was less than half that reported by Hale for the same preparation.

A superficial review of the literature has failed to show other reports bearing directly upon the question, but the evidence in hand would indicate that a further consideration of the methods of toxicity determination is advisable in the case of these drugs, particularly as the intragastric route most closely approximates actual conditions.

METHODS OF TEACHING SEX HYGIENE.*

By Mary Sutton Macy, M.D.,
New York.
Assistant Neurologist, Dental Dispensary; Lecturer, Society of Sanitary and Moral Hygiene.

Thanks to the splendid, unselfish, and foresighted work of the late Dr. Prince A. Morrow, it has become an accepted fact that sex hygiene must be taught, but the determination of wise methods of teaching it, and of the best time for teaching it are still matters of study and debate in many quarters. At the present time, however, there are generally acknowledged to be two successful methods called the physiological and the biological, though to my mind these two are really subdivisions of one complete method. These two—be they associated or distinctive—are variously adapted to different ages or times of teaching. The biological should be, almost exclusively, the method adopted with little children; the physiological may be, almost as exclusively, the wisest method with adults, and a combination of biological and physiological is unquestionably the most successful, according to present experience, during the decade between twelve and twenty-two.

I have been asked to explain to you to-night the physiological method, but I wish to say a word in defense of my statement that this and the biological method are really one. Strictly speaking, biology includes physiology, therefore I think the whole method should be called biological, and the two subdivisions might better be distinguished as physiological and biological or comparative. The evolutionary or comparative method is best for little children and also associatively most helpful in the second decade of life, because it can more easily be graded and modified to meet the years and experience of the individuals being taught, and because it can be easily kept impersonal and still made personally helpful by analogy rather than direct application, and therefore by promoting an unconsciousness of self obviates any tendency toward emotional disturbance, or, if rightly handled, should do so.

The physiological method on the contrary, because of its strictly personal and directly human application, requires a greater balance of emotional self control, and because of the greater and more detailed nature of its information, necessitates a more mature intelligence and greater reasoning ability than is to be found before the middle or last of the second decade of life.

To be most helpful, however, the evolutionary method should have been used to lay a foundation for the physiological, and if sex hygiene is taught, as it should be taught, from early childhood through adolescence, these two biological subdivisions will supplement and dovetail each other as a complete unit.

To come now to the subject matter of my talk to-night, i.e., the physiological method of teaching sex hygiene, let me say, first that a thorough and exhaustive knowledge of general human physiology is essential to any one aspiring to teach by this method; second, a more or less thorough, and at least an intelligent knowledge of general physiology on the part of the pupil is an essential basis for any really helpful instruction; and, third, a true appreciation of the unity of the human mechanism, of which sex, digestion, nerves, etc., are but parts, must be obtained by both teacher and pupil and all tendency to isolate one function and magnify its importance over others must be rigorously avoided.

In presenting the topic as briefly and sketchily as I must to-night, I wish to take it up in three parts:

First, the general physiology of that individual, who for convenience we will call sexless, I mean the boy or girl under eight years of age or thereabouts; second, the physiology of the female sex; and third, the physiology of the male sex.

Obviously I cannot be exhaustive in the time at my disposal and the accompanying chart must help to clear up matters by furnishing headings:

I will briefly sketch the physiology of the child under eight years of age by this tabulation. In nutritional functions throughout its life the growth and development of digestive and absorptive systems has been phenomenal. The mechanisms of digestion and absorption in the average child of eight or ten are perfect and much more mature than many other functions of the body. The child is capable of eating, digesting, and absorbing such foods as may be naturally required by all tissues for growth, for repair, and for work. Unless the glandular functions, especially those having to do with internal secretion, are deranged, the child is also capable of assimilating any food which he or she may digest and absorb. Just here let me emphasize some physiological distinctions in terminology: Digestion, technically means the preparation of ingested food, i.e., food taken into the mouth, for absorption. The preparation of food for absorption includes (1) mastication, or chewing and mixing with saliva, (2) swallowing, (3) gastric, i.e., stomach, changes brought about by chemical activity due to the effects of the fluid called gastric juice, which is the external secretion of the stomach glands, and (4) enteric, i.e., intestinal, changes brought about by further chemical activity due to the effects of several fluids, i.e., intestinal juice, pancreatic juice, and bile, which are all external secretions of important glands. At this point digestion per se ends and the food has so to speak been separated into the sheep and the goats, the former for absorption and use in the bodily economy, the latter for excretion from the bowel as solid waste matter.

Absorption, technically, is the taking up into the
blood and lymph supply of the digestive tract, such of the digested food as can be used by the tissues for the processes of growth, repair, and the production of energy.

Assimilation, technically, means the extraction of nutritive particles from the blood and lymph by the tissues, and their construction into essential elements of the tissues themselves for growth, repair, or work. This function of the body is sometimes too little understood, and as it is a very vital one and intensely dependent upon the integrity of the glandular functions of the body, I may perhaps be pardoned for a brief apparent digression from my outline. Glandular activity is to-day considered to consist of two kinds called external and internal secretions; the first, i.e., external secretion, is composed of some absorbed food elements, extracted from the blood or lymph, which are elaborated within the gland into a complex fluid, and poured out, through a duct, upon some skin, mucous, or serous surface for chemical or mechanical use in digestion, lubrication, or excretion; the second form of glandular activity, i.e., internal secretion, is composed of some absorbed food elements extracted from the blood or lymph, which are elaborated within the gland into a highly complex material and returned from the gland into the blood or lymph stream and carried to more or less remote parts of the body for use by the tissues in promoting assimilation. Internal secretion is a vitally important function and one of the existence of which science has known for a relatively brief period, and therefore we are just beginning to understand it and its tremendous importance to health. So far as we now know all glands have internal secretions; some glands have both internal and external secretions, and I ask you to keep these facts in mind until later.

To return to our so-called sexless child of eight, he digests, absorbs, and assimilates healthily, and these several functions are relatively fully matured. The blood, which is the common carrier of absorbed food for assimilation of the food elements essential for glandular activity, and of the products of tissue waste which must be excreted from the body, must be kept moving and the circulatory functions of the average healthy eight-year-old child are adequate for his purpose. That is to say the heart is strong enough, and the bloodvessels elastic enough to keep the blood moving; the lymphatic glands and other sources of supply for the distinctive elements, which compose the blood, are active enough to keep the lymph and blood rich enough to fulfill their function of carrying and distributing nutritional material to the tissues and conveying waste products from them. The circulatory functions are, however, relatively less mature than the digestive, absorptive, and assimilative functions, and have still much growing to do prior to and during the period known as puberty, which is approaching.

The motor functions of this sexless individual, like the circulatory, are adequate for their purpose. The bones have not yet lengthened to adult proportions, nor the muscles, ligaments, and tendons been toned up to their mature functions, but for all the necessities of child life they are sufficiently serviceable. Just prior to puberty, and during the early part of that time, the bones, etc., take a big spurt in growing, and this appears as though Nature, having been so absorbed in maturing digestion, absorption, and assimilation, suddenly appreciated that motion and locomotion had been neglected and precipitately attempted to make up for former insufficiency.

In the nervous functions of this child of eight we have some very interesting and important facts to notice. His sensory functions per se, i.e., the special senses, and such general sensation as hunger, thirst, fatigue, well being, and the like are matured the motor functions of the nervous system are relatively less matured; the motor functions of his body as a whole, adequate to meet the demands of his age; the associative functions between motion and sensation and vice versa are equal to all emergencies arising in his life; the sympathetic nervous system, which is in reality the guardian spirit and regulator of circulation, digestion, absorption, assimilation, secretion, and kindred functions, is sufficiently mature to maintain the delicate balance and adjustment of functions during health, provided it is not too roughly abused or disarranged by shock, be it fright or other emotional crisis. More of this sympathetic system and its functions in a minute or so.

The mental development of our sexless child is a matter of vital interest and great importance. Up to this time the evidences of psychic development have been largely, if not entirely, motosensory, the emotions such as are directly associated with sight, hearing, smell, and other so-called special senses, and with muscular activity per se. The child is and has been an essential egoist, either absolutely unsocial or assexual in his social activities. Boys and girls have mixed together, played together, indiscriminately and without distinction or differentiation (unless imposed from without by some custom of their adult guardians), and with no true consciousness of the vital difference between boy and girl, with no true feeling of distinctive qualities, abilities, or functions. This attitude is perhaps aptly illustrated by the question of the little girl, "Mamma, how can you tell the difference between brother and me, when we are in the bath?"

So far in the study of this child we find practically no difference between boy and girl. In the remaining group of functions in our chart, we find a kindred similarity: the reproductive functions are latent. All the essential organs of reproduction, including the connections through the sympathetic nervous system and the emotional and other mental nerve elements, are present in the child before eight years of age, but they are latent or inactive in large measure; and they should be so inactive, in the normally healthy child, as to be largely negligible except as the general hygiene of the bath, for instance, necessitates cleanliness. This inactivity is not always a fact, however, because unfortunately accident, lack of cleanliness, tight or improperly fitting clothing, or vicious companionship, or instruction may have resulted in masturbation before the age of eight, and thus have produced a precocious maturity of functional activity in the reproductive system, which is detrimental to the perfect physical and mental balance of the child. These points in sex hygiene must be watched for and guarded against from early infancy: they belong to the pathology and not to the physiology of sex instruction, and
HYGIENE.

(New York Medical Journal.

therefore must wait to-night until later for our consideration.

Before leaving this sexless child allow me to return to the sympathetic nervous system for a few moments and quote from a paper which I read in Brooklyn a year ago on the Value of a Healthy Girlhood.²

Health rests on the wholeness, the completeness, the harmony of the human body and all that is contained therein, both physical and mental. We hear much at times of the health of the whole, and I must emphasize the fact that there is also something to be said on the side of the influence of matter over mind.

The human body is a very complex mechanism, so delicately adjusted that each part works in harmony with every other; disease, mental labor, and even the failure of any one organ has its influence on all others, and frequently shows its most marked evidence of being "out of gear" by some symptoms occurring in organs very remote from the scene of the real trouble. These symptoms are known as reflex, and usually are the result of activity by that part of the human machine known as the sympathetic nerve. Many of you are familiar with the headache, which is apt to accompany constipation; some of you may know from experience the sense of nausea, of giddiness in the region of the head, which sometimes occurs on looking down from a great height. These conditions are reflex effects, remote from their direct cause, and are more or less due to the close and intimate connection of the sympathetic or the parasympathetic nerve, a seemingly misnamed part of our anatomy.

Having made a note of the dependence upon glandular secretions, of digestion, excretion, and assimilation, let me call your attention to the fact that the glands are necessary to make the secretions and throw off the waste; the secretions are necessary to form the food and assimilate the food; the food, waste, and air are necessary to supply the material upon which the glands can work, and the blood is the common carrier.

In order to be an efficient common carrier, the blood must keep moving. It appears to have some automatic apparatus, which keeps reiterating two familiar phrases, "Step lively, please," and "Mind your step." This apparatus is literally the sympathetic nervous system, which automatically governs the circulation.

Examine some time after eating the digestive glands need an extra supply of blood for two reasons: (1) In order to provide extra material for their secretions, since there is no reservoir system which could store up secretions until needed, and (2) in order to provide a larger area to absorb and carry off the digested food, since the reservoir capacities of the stomach and intestines are limited. Very likely the individual, just prior to eating, has been working, and by that term I here include manual labor, physical exertion, and even an aura process of "killing time," which require a large supply of blood in muscles, brain, skin, or other parts of the body remote from the digestive organs. The entrance of food into the stomach, for instance, is like the ringing of an alarm bell, which is heed by the sympathetic nervous system, and two things happen: First, the small blood vessels in the skin, brain, etc., contract their calibre under the influence of the sympathetic nerves in their muscular coats; second, the small blood vessels in the digestive glands dilate their calibre under the influence of the sympathetic nerves in their muscular coats, and, presto, automatically more blood is sent to the digestive system and less to the superficial vessels and other systems. Later, when the individual begins work, the call of the tissues used in that labor is heed by the sympathetic system, and the two processes are reversed, superficial vessels dilate, and deep or digestive vessels contract. Thus you may understand why rest is required for a short time after meals, why hot baths are invaluable immediately after eating even a late supper, since external heat dilates peripheral vessels.

Now, perhaps we have some insight into the reason for calling this nerve sympathetic, and, perhaps, too, we appreciate why the symptom of a disorder does not always appear at the location of trouble but shows up as a reflex symptom. People have been known to have colic who took hot baths after eating; that is an illustration of pain at the seat of disorder; but sometimes, instead of colic, the expression of trouble is convulsions that is a reflex symptom in that case. Convulsions are frequently very dangerous, and it takes a doctor to tell whether they are nervous or a form of something very different and more serious. Wherever convulsions occur: there is disturbance of the nervous system, not only of the sympathetic nerve, since in some forms of convulsions that nerve is not directly involved, but the whole system. It is through the nervous system that the call of the working tissues for nourishment is sent out; it is because of activity on the part of the nervous system that we feel, taste, smell, hear, see, move, and think. Without proper operation from the nervous system the glands would not secrete, even though the blood flowed about them, carrying all the materials they required for their activity. And on the other hand, without sufficient flow of blood containing the requisite food supply, the tissues, of which the nervous system is composed, could not do their work. Here again we see the closed circle. Without a break, it means health. With the least misadjustment of a single link there means incomplete function in all parts, and, if long continued, disability and disease.

Now to turn from the general physiology of the sexless child and add to all we have considered the complexities of sex differentiation, so that we may understand how the child changes first to the boy or girl, and then to the man or woman. Perhaps no section of the human body is more generously supplied with connections with the sympathetic nerve than the sex organs, and this fact may account for the great number of ills which "flesh is heir to," which express themselves in various and more or less remote parts of the body, but which are directly due to some unnatural condition, activity, or inactivity, of the sex organs. This sympathetic nerve connection may also serve to explain if you why slight disorders, such as a light cold, wet feet, or some other more or less insignificant thing, may have a most marked influence in upsetting the regularity of the sexual functions.

Let us consider for a few minutes that lower portion of the trunk of the woman's body called the pelvis and imagine two views of that. One view would show the relative position of the pelvic bone in front, the bladder close behind, then the uterus, the rectum, and back of all again pelvic bone. From this you will understand why it is important to empty the bladder and prevent it from pushing the uterus backward, and also why it is important to keep the rectum empty, by moving the bowel, and so prevent the uterus from being pushed forward. Then, too, you can imagine what must happen to that little cradle of the human race if both bladder and rectum are full; because, as you see, the whole human trunk is packed very closely and all the coils of intestines lie above it. On our other imaginary view, you must imagine the front part of the pelvic bone removed, and behind you could see the muscular and bony structure at the sides, the bladder in the centre and foreground, and the two ovaries and two armlike projections called Fallopian tubes jutting out from the uterus, which lies in the centre behind the bladder.

In both of these views you should have noticed a canal leading down from the uterus, which is called the vagina, or birth canal, and which is the exit through which the baby must come into the
world after being carried for nine months, or 280 days, in the uterine cradle. These organs form what are known as the internal sex organs of woman. The uterus, a hollow, muscular organ, not as big as my hand, is so planned that it will stretch and stretch until it holds a seven or eight pound baby comfortably, and then will contract again to nearly, if not quite, its original size. The ovaries are small (about the size and shape of an almond), and every twenty-eight days, from the beginning of a woman's sex functional life until the end of menopause, each ovary brings to maturity a small ovule which contains the germinal ovum (the egg or seed), and this, if impregnated, will become a child. In order to nourish properly the impregnated seed, when the time for such nourishment arrives, Nature begins a woman's functional life by establishing a habit on the part of the circulation of sending, every twenty-eight days, an increased blood supply to that part of the body to hasten the maturity of the ovule. If not required for the further nourishment of the ovum, some of the extra blood supply is thrown off to assist in carrying away the little excreted germ, and thus we have what we know as the monthly menstrual flow. Nature is always lavish in her provision for life, and especially for reproduction, and she furnishes every month from puberty to menopause a seed for possible impregnation, and when you realize that the majority of women, nowadays, only have at most four or five children, you will appreciate how much value Nature attaches to the ovum that come to full fruition. The seed, which must reach the interior of the uterus through the Fallopian tube and pass out through the vagina, is so small it could not be seen by the naked eye, and yet, as soon as impregnated it contains all the potentialities or latent possibilities of character, of temperament, and of physique, which the future human being will possess.

While still contained within the ovary, or some authorities assert, within the uterus, this minute ovum is susceptible to influence through the action of the maternal sympathetic nerve, and, accordingly, may develop desirable or undesirable potentialities for the future child. Does this suggest to you how careful the young girl, as well as the mature woman, should be not to jar that sympathetic influence by bad hygiene in other parts of the body, or by careless or thoughtless abuse of any part, or parts, of the complex human mechanism? Beside maturing the ovum each month, the ovaries, as ductless glands, produce an internal secretion which has a very important influence in maintaining the healthy function of the whole body; and it is wise for us all to realize that these two little bodies have this dual function, one of which pertains directly to reproduction, the other to the maintenance of the general health.

Unlike the sex organs of the girl which we have just reviewed, the sex organs of the boy are carried largely outside of the trunk of the body, but they have a very close resemblance, in functions, up to a certain point.

The boy has two glands similar to the ovaries, which are called the testicles, and which, like the ovaries, have a dual function, i.e., they have an internal secretion which helps to maintain the general health, and they produce a germinal seed, called the spermatozoon, which must unite with the ovum before the child can be conceived and grow in the maternal organism. These two testicles are suspended in a baglike body, called the scrotum, which, when necessary to force the spermatozoon out of the testicle, can, with the aid of other structures, accomplish this result. The boy also has organs which we may compare to the uterus and Fallopian tubes, and which are contained within the pelvic cavity; they are called the prostate gland and the seminal vesicles, and in them the semen, in which the spermatozoon may live and are expelled from the body, is made and stored for a short time prior to expulsion. In the male the seminal vesicles and prostate gland are in much the same situation as the uterus in the female, that is, they may be compressed between an overdistended bladder and an overfilled rectum, unless the emptying of these organs is habitually and properly attended to, and therefore neglect of these duties will have equally bad results in boy and in girl. Corresponding to the female vagina is the male penis, an organ composed, as is the vagina, largely of erectile tissue and having a canal through which the semen and spermatozoa are expelled. Like the scrotum and unlike the vagina, this penis is outside the body. It also has a dual function, because its canal is the duct by which the bladder is emptied.

Three years ago I had occasion, in lecturing on the care of nervous children, to allude to sexual disorders, and I beg your indulgence to allow me to quote from that paper some passages which may be helpful here in explaining some physiology and a little of the pathology which we must touch on so lightly to-night.

The cleansing of the sexual regions in the boy or girl is of great importance, because, if it is not properly attended to, little particles of a normal secretion collect in the crevices and harden into little sandlike, white balls called smegma. These balls, as the movements of the limbs cause them to rub over the tender skin, set up an itch to which the child naturally rubs or scratches. Rubbing or scratching, or any friction of a certain part of the body, as you all know, draws to that part blood in extra amounts, and thus it follows that, when the child rubs the genitals, the blood is drawn to that region. In two salient particulars the anatomy of the genital region differs from that of other parts of the body which are more frequently discussed and therefore better known to the public. There are proportionately (1) more bloodvessels and (2) more nerve endings in the genitals than in any other portion of the body of similar size. This peculiarity of structure is accompanied by a peculiarity of function; congestion of these bloodvessels produces mechanical pressure upon the nerve endings and this species of squeezing is equivalent to an itch, and therefore, carry to the brain a sensation of pleasure and satisfaction. Hence, we readily see a reason why a child may soon acquire a habit of handling the genitals in order to increase this pleasurable feeling, and thus, even in early infancy, establish a habit of masturbation, or self abuse.

Increased congestion of the genitals is normal in the adult under certain circumstances and at certain times, and anywhere in the body, where increased congestion is normal, its appearance is followed by increased functional activity. This then is what follows masturbation: The genitals become increasingly active, which in childhood—at least prior to puberty—is not at all normal, and in infancy is absolutely pathological. At the age of ten he or she should be taught to acquire the habit of properly

cleansing these parts as a matter of routine; and this should be taught the child with as little ostentation as the cleansing of the hands, teeth, and mouth. The parents should see to it that no nursemaid or other servant inculcated harmful habits into their child.

As the child approaches puberty, and this is the age I particularly wish to emphasize for the nervous child, there comes a very critical era in his or her sexual life, and here at this time is frequently laid the foundation for many subsequent growths and perversions. Between ten and sixteen, too many cases of invalidism are established in girls, and too many cases of ill health and false morals are begun in boys. At about the age of ten or eleven years we find evidenced the first consciousness of sex, the boy's first knowledge of manliness not always constant in him before this time, and the girl begins to show evidence of womanly aspirations. About this time there occurs, normally, in the body a series of changes, which everyone nowadays considers critical in the child's life. These changes are due in part to the beginning maturity of the sex functions. Prior to this period the child has grown in a variety of ways, in some functions more than others, and there exists in the body a balance of equilibrium. Some functions are mature, others immature, and within the next few years a complete readjustment must be effected. In itself this final establishment of an adult equilibrium is no light matter, and the strain of it falls most heavily on the nervous system. Here is the cause of nervousness which appears and develops with puberty, and is due in large measure to the extra stress put upon the nervous system of the child by a combination of the normal pubertal changes and the inefficient metamorphosis with the host of unanswered questions, unsolved enigmas, strange and unaccountable emotions which appear, oppress, and exhaust the child.

With the dawn of maturity in the sexual functions there normally arises a group of emotions, sensations, feelings, and the like, which are entirely new to the child; this is equally true of both sexes, but perhaps, morally at least, more dangerous to the boy. Unless fitting explanation of these phenomena be given the child by the parent, some resistance to, or decision from the boy will be found elsewhere, and to that is that is opened, not only for immoral practices, but also for the establishment of nervous disorders, is incalculable. With the approach of puberty the parent should warn the child that many feelings and problems will arise in this period of life, which the little one will not understand, but which the father or mother can and will explain, if the child will but come and ask for the explanation. In this way there is opened the opportunity for the parent to impress the son or daughter that there is nothing pubertal about the pubertal emotions are due to the dawn of manhood and womanhood, and that they are perfectly normal, natural, and healthy, and that, like other pure emotions such as fear, anger, etc., are to be restrained within healthy limits and not allowed to dominate the will and character. In this way also is obviated the danger of instruction being given to our children by charlatans and unprincipled adults, who play upon the fears, which are constant sequels of new and explained emotions, and who teach the pubertal child that these perfectly normal sensations are the early symptoms of serious diseases, and who lead them, by their fears, into the pitfalls of immorality, licentiousness, and illicit living.

I have said this was a critical period for both sexes. You will say that what I have just stated applies only to the boys, for they alone are led off by such tales into the path of immorality. I tell you it is not so! The girls are led astray quite as surely, not into the paths of immorality, but into lives of invalidism, nervousness, neurasthenia of the like. These unexplained and all pervading pubertal emotions play havoc with the nervous system of the maturing girl upon whom the normal stress of puberty falls heavily. The child is naturally inclined to make changes to undergo in a briefer period of time. Partly because of instinct and partly because of generations of training, the girl does not actively seek any explanation, in the outright, plain-spoken fashion of the boy, but she hears the warnings against these sexual emotions and after a time, or after she forms mental habits—if not physical habits—of self-abuse. By that I mean she, having been taught that it is wrong to speak of sexual matters, infers it is wrong to think of them, and soon convinces herself that the natural emotions, which are followed inevitably and constantly by such thoughts, are sinful and wrong. This leads to a brooding on her own sinfulness, a pathological habit of introspection, and, eventually, by continuous mental self-acusation or self abuse, to melancholia, neurasthenia, or other neuroses.

Sometimes, by force of fortunate circumstances, such a girl is pushed into marriage; and, if her married life is happy and fruitful, she escapes the snare of this habit of mental self abuse. In these cases it requires external care which makes continuous introspection impossible. There are, however, far too many cases where the double standard of morality has allowed the husband to "sow his wild oats," and to acquire a disease which renders the marriage sterile, assumes the full responsibility of the disease to his wife; and to a woman whom puberty has made introspective a sterile marriage is perhaps the worst curse she could have, for she broods more than ever, and her habits of mental self abuse become indelibly confirmed and dominate her life.

For the boy who seeks to learn explanations for pubertal emotions away from home and from watchful loving parents, the road is open, as I have suggested, to immorality and prostitution, but in reality the parents of such a lad are standing with him at the cross roads and passively pointing the way and bidding him "God speed!" down the road to prostitution and disease, or a life of debauchery, misery, and ultimate nervous disease; for, of all the numerous nervous and mental diseases of adult manhood, the largest number are due, directly or indirectly, to one of the so-called social diseases—i. e., syphilis, which is acquired chiefly by illicit intercourse.

Almost the first evidences of sex awakening are mental ones, i. e., the natural segregation of the sexes—boys into "gangs" and girls into "sets." This in reality is a cessation of the former promiscuous mixing of the unsocial child, due to the appearance of a social instinct not unconnected with a vague consciousness of sex differentiation, and usually precedes in slight degree of time the anatomical differentiations and reproductive phenomena, such as appearance of hair on various parts of the body hitherto uncovered by much hair, deepening of the boy's voice, broadening of the girl's hips and her increased bust development, and similar anatomical sex characteristics.

These in turn usually precede by a brief period the appearance of the menstrual flow in the girl, and the first nocturnal emissions of seminal fluid in the boy, which evidences of the establishment of reproductive functions are accompanied, if not preceded by various sexual emotions heretofore unknown, and which are thoroughly disconcerting to the growing mind of the pubertal child, and almost terrifying in their persistence, insistence, and vigor. Not the least distressing of these emotions are those new sensations and the accompanying and alternating feelings of exuberance and of weakness which accompany the earliest nocturnal emissions and the onset of the first few menstrual periods. The unlightened boy or girl does not comprehend the meaning of such phenomena, both physical and emotional, and is most easily led by fears at this time into indescribable acts which may result in permanent injury.

The boy who understands that nocturnal emissions are a normal condition in the experience of his or her sex, and that the experience is an excretion of excessive material, will not be led by his fears of being diseased, to attempt quack treatments for nonexistent pathological conditions, nor will he be tempted to prostitution in order to "prove himself a man," if he understands the true economy of Nature's apparent lavishness.
Nocturnal emissions two or even three times a week, with their accompanying dreams, are not abnormal, and need not alarm the properly instructed boy or man, anymore than the appearance of the menses every twenty-eight days need alarm the girl or woman.

The interesting experiments with the balance table, on which a subject is delicately balanced, and then, while doing a sun in mental arithmetic, sinks by the head, whereas during an imaginary dance, especially if accompanied by some such feet stirring music as the Merry Widow waltz, sinks by the feet—show conclusively the influence of thought in directing the blood supply. If we understand this problem thoroughly, we may also understand the insinence and frequency of sex emotions at the time of sexual awakening, and appreciate the fact that the exercise of will power to control the thought may in large measure cure what appears to be a morbid sexual activity. The boy or girl, who thinks sexually much of the time, is evidencing weakness of will and lack of sex hygiene, and is also promoting excessive sexual activity which may result in some unpleasant morbid consequences later.

The normal sex hygiene, like the normal method of teaching it, consists (1) in a reasonable amount of accurate information on the sex functions, as well as on other physiological functions, such as digestion and respiration, and (2) in giving just as much thought and no more, to the sex functions as one gives to motion, circulation, or any other physiological process.

In closing allow me to call attention to a few very potent dangers in the teaching of sex hygiene. First I must place the danger of introducing pathological data,—by that I mean not only morbid and detailed information about masturbation, sex anomalies, and kindred diseased conditions, but also statistics on the prevalence of sexual diseases, and of prostitution. With young children such data are absolutely inexcusable, and with adults the introduction thereof into sex hygiene talks is a species of alarmist or “yellow” journalism that is to me most repugnant and unnecessary. Especially is this so if the teacher is not a physician, and therefore absolutely well versed and certain of the accuracy of data and statistics. Even when physicians handle such pathological data, meet not infrequently results, and the enthusiasm of lay teachers sometimes carries them into exaggerations of statements which have appalling effects upon the audience. I have in mind especially a case, told me by the surgeon, of a household in which cancer developed in the wife, who was also a mother, and immediate operation was advised. The wife’s maiden sister heard the diagnosis, and either from misinterpretation or misinformation, immediately charged the unhappy husband with immorality. The whole family was thrown into turmoil by the unfounded accusation, and it was with greatest difficulty that the matter was adjusted at all. Finally the sister in law was convinced that cancer was not a sexual disease, concerning which she had recently heard appalling statistics cited by a lay lecturer on sex hygiene, and the misunderstanding was glossed over, but unhappiness and distrust persisted for a very long time.

Second, I must place the danger of overemphasis on sex. The pendulum has swung so far from the old fashioned silence on all sex topics that we are in serious danger of saying too much and talking too often, without making plain the facts that (1) the reproductive function is only one function of the body, (2) that it is physiologically no more vital than any other, and (3) that it is closely associated with and interdependent upon all other mechanisms of the human machine.

Third and last I must mention the danger of too detailed information, and in this relation permit me to quote from the report of the special committees of the American Federation of Sex Hygiene, on Matter and Method of Sex Education, as follows: “Sex instruction has a purely practical aim and should be strictly limited by this aim. Its purpose is to impart such knowledge of sex at each period of the child’s life as may be necessary to preserve health, develop right thinking, and control conduct. Its aim is both hygienic and ethical; and whatever knowledge of sex and of sex relations in human life is not necessary at any particular period of the child’s life for these ends should not be imparted at that period.”

101 West Eightieth Street.

A CLINICAL STUDY OF THE LEUCOCYTES.*

BY GRAHAM E. HENSON, M.D.,
Jacksonville, Fla.

It is only comparatively within the last few years that laboratory methods have been used by the bedside worker, and it is not so long ago that the laboratory worker was looked upon as one to whom we could refer in a few obscure and uncertain conditions. Not so to-day however, and the bedside man that will not avail himself of practical laboratory methods cannot expect to succeed as a diagnostician. In no direction has modern medicine made greater progress than in the study of the blood in disease—hematology.

Starting some years ago with the simple knowledge that in certain pathological processes we have an increase of the white cells, all increased counts grouped under the general term of a leukocytosis, we have advanced to the point of knowing that in a great many diseases we have a definite blood picture comprised of an increase or decrease of the various white cells, this picture sometimes being positive evidence of certain disease, and at other times a valuable link in the chain of evidence that a specific pathological process exists. The field is a broad one and I shall only attempt to bring out a few of the valuable suggestions we may receive from an absolute and from a differential count of the white blood cells.

In normal blood we find approximately 7,000 white cells to the c.mm.; there may be however a variation of one or two thousand in either direction consistent with fairly good health. These cells are classified under two distinct groups, the mye-

*Read before the Florida Medical Association, Miami, May 14-16, 1913.
logenous group—cells originating from the bone marrow, and the lymphogenous group—cells originating from the lymphatic tissue, and in normal blood they hold a certain numerical relation to each other.

Under the first group are included the polymorphonuclear neutrophiles, eosinophiles, mast cells, and large mononuclear cells; the second group includes all of the lymphocytes. The numerical relation of these various cells is as follows: Polymorphonuclear neutrophiles, sixty-five to seventy per cent.; large lymphocytes, two to six per cent.; small lymphocytes twenty to thirty per cent.; eosinophiles, one to four per cent.; mast cells, 0.05 to one per cent. However, just as the total white cell count may vary within certain limits in good health, so also may be seen a certain variation in these percentages. In addition to the cells enumerated above as occurring in normal blood, we find in certain diseases still another white cell—the myelocyte. It belongs in the myelogenous group, being a mononuclear neutrophile, in fact, later in development it emerges as the polymorphonuclear neutrophile.

An absolute white cell count is made for the purpose of determining the total number of these cells to the c.mm. If the count be above normal the increase may be due to a leucocytosis (polymorphonuclear neutrophilia), a lymphocytosis, an eosinophilias, or a myelemia; we then by a differential count determine what change from the normal numerical relation of these cells to each other exists, or in other words find what cell is responsible for the increase, and only by so determining are we able to determine the full significance of a high white cell count. If the count be below the normal, it is termed a leucopenia.

LEUCOCYTOSIS.

There has been a good deal of confusion in the past as to what really constitutes a leucocytosis. Cabot (1) defines the term as, "An increase in the number of leucocytes in the peripheral blood over the number normal in the individual case, this increase never involving a diminution in the polymorphonuclear varieties; but generally a marked absolute and relative gain over the number previously present." Emerson (2) writes, "This term was meant an increase above normal of the white cells of the blood, but the term now means a transitory, symptomatic, absolute increase of the polymorphonuclear neutrophiles especially, in the peripheral blood above the maximum that is normal for a given individual in the condition in which he at that time finds himself." This author gives the following good illustration of a true leucocytosis, as the term is now applied, we mean an absolute increase of the polymorphonuclear neutrophiles, a clear distinction from the blood picture of a leukemia, in which, while there is an enormous absolute increase of the white cells, there is little if any increase in the polymorphonuclear neutrophiles.

In considering the significance of a leucocyte count there are many conditions that have to be taken into consideration. Thus we may be treating some disease in which a leucopenia may be present, but some complicating process may produce a leucocytosis; but that leucocytosis may not necessarily mean a high count. Illustrating this important point Emerson reports a case of typhoid fever with a white cell count of 1,000; a complicating parotiditis brought the count up to 3,200, which constituted a leucocytosis for that person at that particular time. Again, a poorly nourished and ill fed person may have a normal count in their usual health state of 3,000 or 4,000 instead of 7,000; in other words, such a person may have a chronic leucopenia. While this constitutes a pathological condition, at the same time, if in such a person an attack of acute appendicitis developed a leucocyte count showing ten, or even eight, thousand would constitute in that individual a very decided leucocytosis. Turck (3) in considering The Hematological Reactions to Infective and Inflammatory Processes, very tersely sums up the situation by saying: "It seems absurd to presume that the white cells of a feeble and anemic child of ten will show exactly the same reaction in infections of equal scope and virulence, as the cells of a strongly robust man of forty, yet the literature is teeming with definite standards of white cell counts applicable to definite conditions." There can be no question that before the full significance of a leucocyte count can be interpreted that it is requisite that we have a knowledge of the personal standard, as what constitutes in one individual a leucocytosis may be a normal count for another and vice versa. It is not, of course, practical in private practice to have on record a white cell or a general blood picture of all of our patients, but effort should be made to secure such records just as far as such procedure is practical, and as Drysdale (4) writes: "Every opportunity should be taken when an occasion offers, as when a patient enters a hospital, to determine by routine examination the standard for each individual, so that should the examination of the blood become of importance we may start with a better foundation to our knowledge." A great deal of care should be maintained in drawing deductions from low white cell counts where we may have reason to expect high counts, and an absolute count showing a decided increase in the white cells should not be pronounced a leucocytosis, until after a differential count has been made and the fact established that there is a decided increase in the polymorphonuclear neutrophiles, for in splenomyelogenous or in lymphatic leukemia the white cells often reach many thousands above normal, so that a high white cell count may be very wrongly construed unless it is definitely determined whether this increase is among the polymorphonuclear neutrophiles or other white cells. The full significance and importance of the differential count is well illus-
trated by Turck (3), who quotes a case of noninflammatory appendicitis clinically typical in which the white total count was 40,000, but the differential count showed that the eosinophiles constituted fifty per cent. of the total white cells. The appendix was histologically normal, but its cavity was filled with Oxyures vermiculares.

A leucocytosis may be physiological or pathological. The former we will not dwell upon other than to say, in passing, that the condition occurs after the ingestion of food, is seen in the newborn, is frequently present in the pregnant state, and is often observed after violent exercise or following cold baths.

A pathological leucocytosis may be (a) posthemorrhagic, (b) inflammatory, (c) of malignant origin, or (d) due to experimental influences.

(a) Posthemorrhagic. Following a severe hemorrhage the white cells within a few minutes will be found in excess, numbering from 10,000 to 18,000. It is supposed that the increase is due to the fact that with the volume of blood reduced the tissue lymph which goes into the vessels takes with it many white cells.

(b) Inflammatory. The conditions in which we may find an inflammatory leucocytosis are very numerous, and I shall only mention here those in which we may require this link of evidence in establishing a diagnosis. These are pneumonia, appendicitis and all abscess formations, the suppurative stage of smallpox, acute arthritis, acute cerebrospinal meningitis, together with puerperal and all other septic conditions. The time at my disposal does not allow a separate discussion of the diagnostic value and significance of a leucocytosis in each and all of these conditions, but the extreme value of white cell counts in all cases of suspected appendicitis is such that I will, in a brief manner, discuss the deductions to be drawn in such cases. Every case of appendicitis will not show a high leucocyte count, and it is probable that too much attention has been given to the total count and too little to the differential. It is not in the marked case with a walled off abscess, presenting all the symptoms and giving the history of a pustular appendix, and showing a total leucocyte count of thirty or forty thousand, that we need the blood examination to confirm a diagnosis already made, but it is in those atypical catarrhal inflammations, in which the total count may be but little if any increased, but in which a differential count shows the polymorphonuclear neutrophiles with a proportion of from eighty to ninety per cent. In other words, where we may be uncertain in such conditions we have a valuable factor in the differential count, showing whether or not there is any increase of this particular cell, such increase indicating at all times in abdominal conditions serious trouble.

(c) Leucocytosis of malignant origin. The total count in malignant tumors is generally high, ranging all the way from 8,000 to 30,000, being more pronounced in sarcoma than in carcinoma. The polymuncturals are always largely increased showing a true leucocytosis. An eosinophilia may also be present. In operative cases following the removal of the tumor the leucocyte count drops to normal, or at least becomes materially lowered. A return of the leucocytosis may be taken as an indication that a recurring malignant involvement is taking place.

A pathological leucocytosis due to experimental influences, therapeutic influences, and shock is described in the textbooks, but it is not sufficient significance to make a discussion of the varieties worth while.

LYMPHOCYTOSIS.

By a lymphocytosis is meant an increase of the lymphocytes both absolute and relative. A differential count showing an apparent lymphocytosis should not be pronounced such, until an absolute count shows that there is an absolute increase, as the apparent increase shown in a relative count may be due to a diminution of the polymorphonuclear neutrophiles, a common picture in persons of poor health and low resistance. The blood of a child below five years always shows a lymphocytosis, so that care has to be taken in arriving at conclusions from the blood pictures of these children. Of especial significance in the diagnosis of malaria is an increase of the large mononuclear lymphocytes. A very marked increase of the small lymphocytes is seen in whooping cough; it is a valuable symptom and may be seen early in the catarhral stage of the disease. The most pronounced lymphocytosis is seen in acute lymphatic leukemia in which the total count may run as high as 150,000, and Cabot (1) even reports a case showing the enormous total count of 1,480,000 with the lymphocytes holding the high percentage of 87.6 per cent. Lymphocytosis is also a valuable diagnostic link in hereditary syphilis.

EOSINOPHILIA.

An eosinophilia, or an increase of the eosinophiles, is of especial significance to the general practitioner of the South. It is always present in hookworm disease and in hookworm infection, and a routine examination of the blood will result in many carriers being found, possibly where the infection was not suspected. It is not uncommon to find individuals suffering with uncertain symptoms, general malaise, or a condition bordering on neurasthenia, and an examination of the blood in these cases will often disclose an eosinophilia; with this clue the feces are examined and the diagnosis completed. Among other conditions in which an eosinophilia may occur may be mentioned myelogenous leucemia, other intestinal parasitic diseases, many of the skin diseases, malignity and bronchial asthma. In the latter disease the symptom is of especial value in determining that the attacks are of bronchial origin.

LEUCOPENIA.

In contradistinction to the various blood pictures already mentioned, showing an increase of the various cells, is leucopenia, a condition in which the white cells are reduced in number. It is constant in both typhoid fever and chronic malaria, and is nearly always present in acute malaria. A differential count will show an increase of the small lymphocytes in typhoid fever, while in malaria there will be an increase of large mononuclears. In persons not suffering with acute disease it is an index of low vitality and poor resistance. It is also seen
in measles and tuberculosis, being an especially valuable symptom in the early stages of the latter disease.

In conclusion I would urge the necessity, when depending on the blood picture, of making both absolute and differential counts of the white cells, and to abstain from the too common custom of relying on one to the exclusion of the other.

BIBLIOGRAPHY.

NEOSALVARSAN AND MALARIA: A PERSONAL EXPERIENCE.*

With Some Reflections on Suicide.

By JOHN ASHBURTON CUTTER, B.Sc., M.D.,
New York.

Ehrlich in his address before the recent International Medical Congress, in London, said that the step from the laboratory to the clinical room was a dangerous one involving the use of the products of the laboratory on the human body with its manifold involvements of idiosyncrasies with which the general practitioner has always had to contend, I am for this and other reasons making this presentation as clinically complete as possible.

My first infection with malaria occurred in 1888 while on some special medical work in Kentucky and while residing on a stock farm near the Ohio river bottoms; the usual prodromata of lassitude, irritability, and pain in lower back from liver and spleen engorgement appeared; the onset was marked by a severe chill followed by fever; all of which were apparently promptly cured by quinine, chologogues, and the fact that I was then twenty-five years of age. From that time till my next infection in 1898 I was free from ague. This second infection was by mosquito bites after a hard day's work in the month of August while waiting for a trolley car on the banks of a river in an adjoining State; five days later the prodomata developed; I had a severe chill the next day followed by fever. Apparently I have not been free from this second infection, for spring and fall I would be more or less troubled with a mild fever and general debility. Eight years ago, in one of these attacks, my daily temperature was over 102° F., and a medical student called my trouble typhoid; I called in Dr. Alfred F. Brugman who from my history and enlarged spleen and liver made a diagnosis of malaria. I had lost twelve pounds in this illness. Later I was under the care of Dr. Arthur B. Townsend with similar symptoms and received the usual treatment of arsenic, quinine, nux vomica, capiscum, and chologogues.

The latter part of July, 1912, I was with some friends at Coney Island on a Saturday afternoon and evening and was badly bitten by mosquitoes: the following Saturday, after a day of pain in the back, a profound chill developed which after six hours was followed by fever. I also had a heavy cold on the lungs and again lost twelve pounds in weight. I had been under the care of Dr. John E. Rae for right auditory nerve trouble, and during his absence on vacation, Dr. Robert L. Loughran took over the ear work; at this time I took sixty grains of quinine in three days. After a week the malarial condition apparently subsided, but my ear has needed treatment off and on ever since.

The latter part of June, 1913, I experienced a renewal of my old trouble though with no recollection of reinfection; my medication consisted of five grains of quinine daily in a bromide solution, grain per grain, and from a sixteenth to a tenth of a grain of arsenic. Hecutu, anorexia, and depression of spirits were constantly present; my medical work was done under compulsion and my weight was gradually diminishing. Finally my temperature rose to 101° F. (oral), though before and during this last indisposition it had been elevated only about a degree. The pain in the back was at times excruciating and the physical weakness was increased. My memory for anything except actual medical work became greatly impaired. Dr. Arthur R. Braunlich on examination found my spleen and liver swollen. Doctor Rae being again out of town, the next morning I consulted Doctor Loughran, who threw up his hands and said as to the use of from twenty to twenty-five grains of quinine daily: "You know the danger, Doctor." I then dropped in on Dr. Winfield Ayres for consolation, and on his remarking my woebegone condition I told him my story; this was on August 8th. He promptly advised neosalvarsan, and I as promptly got on his operating chair and received in the left arm 0.50 grame of neosalvarsan in about six ounces of solution. This produced some pain in the front of the left shoulder and some discomfort or oppression about the head; this treatment was repeated three days later with less discomfort about the shoulder, the injection being made in the right arm. Two days later an injection was made in the left arm of 1.20 grammes of neosalvarsan followed by the same pain in the left shoulder but not so much discomfort about the heart. This cardiac discomfort could hardly be described; it was not a pain, but a feeling as if something was flowing through the blood vessels toward the heart, and there was an oppressive feeling in the left chest cavity in or above the heart. Doctor Ayres made all his injections with great care, expressing pleasure that he had a medical man to give him symptoms, and checking the flow of the solution from time to time.

An hour after the first treatment intestinal colic appeared and after two hours of decided discomfort I had to take a quarter of a grain of opium for relief; as I had been eating so little for the past weeks my bowels were distended by gas, and for nearly ten days after the first treatment the intestinal tenesmus from the tonic action of the arsenic was more or less persistent especially after the third treatment when I spent a restless night. and the next day suffered from muscular soreness over the whole body as if I had been engaged in severe manual labor. The intestinal tenesmus was

*Presented to The Medical Society of the Borough of The Bronx, September 16, 1913.
so great that I could not stand erect but walked bent over for two days like a very old and feeble man. My temperature since the first treatment has not been over 99.8° F., and if any fever has been present the temperature has been usually from 99° to 99.6° F.; any exertion beyond the absolutely necessary work of practice would bring this on; for instance, being shorthanded, an half hour of work at a typewriting machine would cause much pain in my back, and an elevation of temperature. The day following the third treatment I was mildly jaundiced especially on my body, suggesting to my mind acute fatty degenerative changes in the liver.

Doctor Ayres suggested strychnine in one thirtieth grain doses, and one dose almost took the top of my head off so to speak and caused a slight rise in temperature. Sixteen days after the last intravenous injection, feeling very wretched, I dropped in on my neighbor, Dr. Frank C. Hollister, who also thoroughly examined me and found a subnormal temperature and a general cachexia; but the liver and spleen being normal in size he advised a tonic mixture of nux vomica, quassia, and gentian compound, six drops of the tincture of nux vomica to the dose. This at first was highly stimulating but I am now taking two or three doses during the day; how much of the tonic action of the arsenic remains I cannot say. The anorexia being absent I am now making flesh, but having lost twenty pounds, I have not as yet regained my usual weight, but my general outlook on life is much for the better.

How much of the cachexia noted by Doctor Hollister was due to arsenical poisoning cannot be determined. Doctor Ayres's doses were heavy. Tie, however, knowing me intimately was quite disturbed by my condition and felt there was nothing to be gained except through active medication. I have given a rather full history for the benefit of the clinicians who may read this.

Curiously, when I was receiving my first intravenous injection, Ehrlich was addressing the International Congress, in London, on its value in malaria, stating that quinine sometimes lost its hold on cases and, after the exhibition of neosalvarsan, that quinine resumed its effect. As before noted, quinine in large doses was interdicted in my case; there are others who cannot use it; I know of one case in a Southern State in which the patient was in a state of collapse for twelve hours, needing artificial respiration and oxygen, the collapse being caused by the oral exhibition of two grains of the drug.

An editorial in the Journal of the American Medical Association of August 30, 1913, calls attention to the use of salvarsan in recurrent fever and frambesia and its apparently favorable employment in scarlet fever, smallpox, glands, Vincent's angina, Aleppo boil, and amebic dysentery.

A recent writer, whose name I have forgotten, states that malaria in its worldwide relations kills more people than any other one disease. How correct this observation is I know not. Some pathologists state that the degenerative changes causing death are due to toxines set free by the quinine killing the plasmodia.

This I have to say: A man in the condition I have been sees little in life; the dragging feet, irritability, pain and discomfort in the back, loss of appetite, and hebetude, especially shown in weakened memory, make him irresponsible if he commits suicide. How many cases of feto de se are caused by chronic malaria no one naturally knows, but it is my profound conviction that more instances of such form of death should be charged up to said cause. Personally I do not care to thus end my life.

How thoroughly I am cured I do not yet know, but I have taken absolutely nothing in the line of malarial medication except tonics. If I need further treatment by neosalvarsan, I am ready for the ordeal. Parenthetically, let me state that the plasmodia have not been found in my blood. It appears to me that we are opening up a new therapeutic range which, after careful examination and logical diagnosis, can be freely entered upon.

Finally, I thank Ehrlich the discoverer, Ayres the user, and the other medical men who have been so kind to me.

Case reported by Dr. Winifred Ayres:

Case. Patient, aged forty years, a publisher, of Texas, was referred to me on August 15th by Dr. I. N. Hill who stated that the patient was a pronounced hypochondriac; that a Wassermann reaction was negative and that a search for malarial organisms had also been negative. The patient stated that he had had several very severe attacks of malaria and that at irregular intervals he was subject to mild chills and fever; that he had a headache almost every afternoon lasting three or four hours. I found his spleen slightly enlarged, and his liver enlarged and a little tender. With nothing else to account for the chills and fever I concluded they must be due to chronic malaria. I gave him 09 grammes of neosalvarsan on the 21st and repeated the same on the 25th; after neither was there the slightest reaction or inconvenience; there was distinct improvement after the first treatment and the last time I saw him—for the 30th—he stated that he had not felt as well in years; that his headache had entirely disappeared as well as his indefinite pains; and that he had an appetite and enjoyed his food—a condition he had known in at least five years. The patient is now in Texas and is so sure that the neosalvarsan cured him that he intends to have it used again if he is reinfected.

October 16, 1913. The writer wishes to report, that the patient has used no further malarial medication; that his general condition has steadily improved; and that the conviction of the growing field of usefulness of Ehrlich's blood sterilizer is strengthened.

266 West Seventy-seventh Street.

A PLEA FOR OILY INJECTIONS OF SALVARSAN.

By HERMANN G. KLOTZ, M. D.

New York.

Principally in view of the occurrence, in a number of cases, of abscesses at the site of injections of oily suspensions of salvarsan and neosalvarsan from three to twenty-four months after a treatment Dr. H. H. Hazen, of Washington, D. C., in a paper entitled, Oily Injections of Salvarsan. A Warning (Journal of the American Medical Association, May 24, 1913), advocates that the intravenous method should be the only one employed. I am personally indebted to Doctor Hazen for the information that he prepared the injected fluid immediately before use and that all possible precautions as to sterilization and aseptic conditions were applied, so that he cannot but feel that the salvarsan itself was responsible for the abscesses. In the opened ab-
scesses no trace of the salvarsan could be found and in all the cases the therapeutic effect had been marked. Hazen states that he finds it rather difficult to account for these late troubles (particularly for the breaking down in one of his cases of both buttocks three months after an unilateral injection) except on the hypothesis that the injected material is toxic to the tissues at the site of the injection and that this dead tissue, if not absorbed, may act as a foreign body. Various investigations have indeed demonstrated that salvarsan causes considerable local injury to the tissues. Tomaszewsky, for instance, in a paper, On Experimental Investigations on the Final Outcome of Intramuscular Injections of Salvarsan (Charité Annalen XXXV) states that pathological and anatomical examinations of intramuscular injections of salvarsan in all instances have revealed extraordinarily severe tissue changes in muscles, fat, and connective tissue, necrosis of nerve fibres as well as thrombosis of all bloodvessels within reach of the injected mass.

Concerning the fifty-two oily injections of salvarsan and neo-salvarsan made by him, Hazen admits generally excellent effects upon the lesions and on the Wassermann reaction, in the majority of instances also excellent immediate results with regard to pain and disability: twenty injections were practically painless, only twelve caused pain that was at all severe; only three patients lost time for work, one about ten days, the other two not over two days each. "There has not been a single patient who was not willing to take another injection." Four cases presented complications shortly after injection; in two slight abscesses of no particular importance developed, and in one peripheral phlebitis about two weeks later: the most serious accident was pulmonary embolism in one case from which the patient recovered within about two weeks.

My own experience with oily injections of salvarsan was in part derived from a number of injections made in my service in the German Hospital. A freshly prepared suspension in olive oil was employed under the same precautions as to sterilization and asepsis as practised by Doctor Hazen. In none of these cases were any immediate or later untoward symptoms observed, only a moderate swelling around the seat of the injection and some sensitiveness on pressure was usually present for a few days. In private practice I find that thirty-three injections of identical character were administered since February, 1911, to twenty-three patients. One patient received altogether five injections, one four, three each three, two received two, and the rest one each. In three cases only have I been unable to ascertain the immediate consequences of the injections owing to the fact that the patients had come from outside New York. In a number of cases the only reason for the administration of the salvarsan was a positive Wassermann reaction in the absence of other symptoms in the later stages of the infection. Where any specific lesions were present they belonged to the late secondary or gummatous class, mostly those that had proved refractory to mercurial treatment: the therapeutic effects were excellent as a rule. Otherwise the results were very similar to those observed by Hazen. After twenty-three injections hardly any discomfort was experienced except the swelling and sensitiveness on pressure during the first days which one must naturally expect under the circumstances. They usually reached their maximum on the third or fourth day to gradually disappear not later than the end of the second week, although in a few cases a more or less hard but only slightly sensitive node did remain for a longer period, mostly when the patients had neglected to avoid any intense muscular exertion within thirty-six hours after the injection. In six instances a sharp pain was felt immediately extending from the seat of the injection down along the extremity, which persisted with diminishing intensity for several days, in the worst case for ten days. As far as I know none of the patients was actually disabled from attending to their business, perhaps largely due to the fact that preferably the injections were made on Saturday afternoon, giving a sufficient period of rest until Monday morning. I did not see phlebitis, abscess, necrosis, and pulmonary embolism, with the symptoms of which I have become sufficiently familiar since 1886, through the injections of insoluble mercurial salts, mostly the salicylate and calomel, the latter being much more liable to cause pain and produce nodes. Altogether I can safely state that the local subjective and objective effects incident to salvarsan injections have not essentially differed from those after insoluble mercurial salts, except as far as they were inevitably affected by the larger quantity of the injected fluid. Among the early cases of mercurial injections, like most observers, I saw a few aseptic abscesses but none afterward among thousands of injections; a case of superficial necrosis and some cases of pulmonary embolism I have published (Archiv für Dermatologie, Festschrift für Pick, 1898, and LXIV, 1903).

The insoluble mercurial injections met with much opposition, particularly in this country, more or less general for a long time, often quite severe and almost fanatic; as late as 1907 the method was publicly assailed as cruel, dangerous, and unscientific, soon after to be generally recognized as the most efficient and legitimate method of mercurial treatment, although the shortcomings and incidental unavoidable disadvantages had not been entirely eliminated.

In view of this experience with the injections of insoluble mercurial preparations, while the profession certainly must be thankful for the candid and conscientious publication of unfavorable incidents of any method of old or new treatment, it seems hardly justified as yet to peremptorily condemn the oily injections of salvarsan, certainly not until one has very carefully and without prejudice considered the question whether this method does not offer sufficient advantages besides, and even over the intravenous method, which would fully justify its further recognition as a legitimate way of administering salvarsan.

When the edict was sent out by its author that salvarsan should be exclusively administered by the intravenous method, it was clearly understood that this preference was given because the subcutaneous and intramuscular injections of alkaline and neutral solutions heretofore employed were extremely
THE TREATMENT OF CHRONIC URETHRITIS.*

By Saul Steiner, M. D.,
New York.

Before entering into the discussion of the treatment of chronic urethritis, it is necessary to know when a gonorrhea is chronic. In other words, when does the acute stage end, and when does the chronic stage begin? The importance of this point is evident, when we take into consideration the fact that the treatment, in these two conditions, is entirely different.

We do not want to go into particulars concerning the details of these two stages of the disease; but we will admit that, roughly speaking, an acute attack of urethritis passes into chronicity when the discharge disappears or becomes very scanty, when the acute symptoms subside, when the urine contains only a few persistent shreds, or when the patient complains of a morning drop, or of some pain which is localized at some part of the urethra; all these after eight or ten weeks have passed, since the appearance of the initial symptoms. Pathologically, we could consider a urethritis chronic when the gonococci remain for a long period of time in the tissues or follicles, in spite of the treatment.

For the present I will pass over the symptoms and their causation: namely, the anatomopathological...
cal changes of the urethra, characterizing chronic urethritis. In the course of this paper we will take these symptoms up separately, we will see what anatomical conditions they are due to, and then we will discuss the treatment.

One fact must be stated, and perhaps we will repeat it a few times, but that fact cannot be sufficiently emphasized, the most important thing in the treatment of chronic urethritis is a correct diagnosis. We must not be satisfied with a general diagnosis, but we must point out with our finger the real cause of the trouble.

A patient presents himself for consultation with the complaint that every morning, upon arising, a drop of pus escapes through the meatus. Now, in order to treat this patient intelligently, we must know the virulence and the size of this drop.

Does it come from the anterior or posterior part of the urethra, and, moreover, what portion of the latter?

We first ask the patient whether he has had, in the course of his disease, an orchitis, epididymitis, or cystitis, which would prove a deep infection; when the patient tells us of having had repeated attacks of urethritis, we can safely suspect a deeply seated infection.

Suppose he does not. Then we squeeze from behind forward different parts of the anterior urethra, first the pineal portion, then the scrotal, and finally the perineal portion, trying thus to bring out the drop. If we do not succeed, it means that the patient must have just previously micturated, and consequently washed out the canal. We inquire about the time of the last micturition. This will indicate rather roughly how long it took that drop to form; if we cannot be present when the patient passes his first urine, we give him two slides, instructing him how to collect the drop. When we have received it, we examine it microscopically, and one of the following conditions may be seen: Intracellular gonococci present; extracellular gonococci present; or, no gonococci present. If intracellular gonococci are present, it is an indication that there is a part of the urethra which is inflamed and harbors a nest of microorganisms. Now the diagnosis is not yet made; it is not enough to say that the patient has a chronic urethritis with gonococci present. The principal thing is to find out where this spot is located—the spot or spots which harbor these microorganisms so long.

Different methods are used to find the precise locality of the infection. A good test is "the glass test" of the urine. The "two glass test" is very unreliable. A very reliable method is Wolbarst's five glass test, which is so well known by all of us that we will not go into details. Next we take a metallic sound—the largest the meatus will admit (if the meatus is contracted, it is advisable to perform meatomaty before any treatment is begun) —and introduce it up to the prostatic urethra, not further; then, by pulling the penis along the sound, thus stretching the urethra with the left hand, we proceed, with the fingers of the right hand, to a regular and careful palpation of the urethra; thus we detect painful points, infiltration of the mucosa, enlargements and infiltrations of the follicles, granulations, etc. After this external examination we introduce the urethroscope and examine carefully the whole length of the canal, verifying what information, if any, we get by palpation.

Then only can we say that we have made the right diagnosis, that we know the lesions and feel sure of what we must do for the patient. If we find congestion of the mucous membrane with no other visible lesions, we irrigate the canal with a solution of silver nitrate, or of potassium permanganate. I prefer a solution of potassium permanganate of various strengths, beginning with one in 6,000 up to one in 1,000 for the anterior urethra, and use the silver salts when the gonococci are extracellular. If we find granular patches we touch them through the urethroscope with a solution of silver nitrate up to ten per cent. in strength. Thalline sulphate in five per cent. solution is less irritating and more suitable for posterior urethritis. Solutions of copper sulphate are very irritating and not reliable.

If we have to deal with ducts which lead to paraurethral follicles, it is best to go into them with a very fine probe, and after dilating or opening them cauterize them with the galvanic or the high frequency current. In using these currents, one must be very careful: they are very dangerous even in experienced hands. Instead of using the electric currents I try to open the mouth of the follicle with a fine probe, and afterward, by introducing the metallic sound I make a thorough and strong massage with the fingers on the outside of the urethra, thus squeezing out whatever secretion is accumulated in the follicle. It is surprising to see the perfect results that can be accomplished by this method. The gonococci are imbedded in that follicle, and the keratinized tissue, newly formed over it, prevents the microorganisms from coming to the surface to be extruded. They stay there like prisoners, and two things may happen: Either they may proliferate, multiply, and form minute abscesses with all their complications (the abscesses may open toward the skin, causing fistula, may open into the urethra, bringing about a recurrence or a recidivation of the disease—urethritis by an auto-infection), or they may undergo resolution—that is a digestion of the microorganisms by the leukocytes in these glandular retentions. The detailed technique of cleansing the urethra is this: The urethra is irrigated with potassium permanganate, about 500 c. c. of a one in 4,000 solution. Then about 300 c. c. of the same solution is injected into the bladder. Massage the urethra as already described, and then let the patient freely void the solution which is in his bladder. This will wash the whole surface of the urethra, bringing out from behind forward everything that previously was squeezed out from the follicles and brought to the surface by the massage. In this way we are not afraid of causing a fresh infection, because the gonococci squeezed out of the follicles are not allowed to remain in contact with the mucosa for any length of time. The same procedure is used when the microscope shows extracellular gonococci. But here instead of using the permanganate solution it is best to use a silver solution, which has a more direct influence upon the gonococci.

In the third case, namely, when the microscope does not show any gonococci at all, the treatment is different. But considering that in posterior
urethritis the condition is similar to that which we find in the anterior urethra we will discuss the treatment of this condition a little later when we study posterior urethritis.

There are cases of chronic anterior urethritis in which we cannot find any localized lesion, no matter how carefully we look with the endoscope, and still the patient has a very slight discharge in the morning, or he complains only of a pasting together of the lips of the meatus, without the microscope showing any gonococci in the discharge. In these cases we have most probably to deal with a catarrhal condition, the discharge containing a great number of epithelial cells, flat cells, and mucus. These patients do very well under the use of an astringent solution—especially a one per cent. solution of zinc sulphate—given by injection, by the physician, or by the patient. I personally do not favor the idea of allowing patients to use injections, for many reasons.

It is proper to mention here the objection to the use of urethral bougies made of cacao butter containing medicinal astringents or antisepsites. I once saw a case where a patient had used one of those bougies. In twenty-four hours it had provoked such an inflammation that the urethra was like a real fountain. It was dropping every two seconds a large, thick, yellow drop of pus. Micturition was extremely painful. Under the microscope the discharge showed very few gonococci, but an enormous number of micrococci, streptococci, and staphylococci. Evidently the bougie was not aseptic.

I want to mention here something about instillations in the anterior urethra. There are some chronic conditions in the anterior urethra in which nothing else is found but a thickening of the mucous membrane, a thickening which sometimes is very marked and which involves a large portion of the length of the penile urethra. This thickening is due to an infiltration of the mucosa which leads to the formation of additional keratinized tissue; it is not properly a stricture. In these cases we massage the urethra actively over a metallic sound, and after irrigating the canal as previously described, we instill from five to ten c. c. of a 0.5 per cent. silver solution, or a five per cent. thalline sulphate solution into the urethra, taking care not to push the liquid too strongly, so that the posterior urethra shall be protected, then we tie the penis right behind the sulcus glandis with a strip of bandage. The liquid should be retained about half an hour, or longer. I must admit that this procedure is quite painful, but most patients stand it well and derive great benefit from it. Undoubtedly massage and the use of larger sounds will do more good than the instillations, but the former must be employed every third day over a long period of time.

Quite often the pus is caused by a stricture. In long standing cases and mostly in patients with repeated attacks of urethritis, pathological changes occurring in the submucosa form a narrow constricting band which diminishes the lumen of the canal. The portion of the urethra behind the stricture, which is composed of strong connective tissue and consequently undilatable, being continually forced by the stream of urine in the act of micturition, will give way gradually, become dilated, and, sometimes, form a pouch. In this pouch the inflammatory exudates constantly remain and cause erosions and granular patches which harbor the microorganisms. With the urethroscope we can see the change of color in the morbid area—a dull gray with tenacious stripe.

From this, it is plain that the first step in the treatment of such conditions is to remove the stricture, afterward cauterizing the morbid surface behind it. It is of no use to treat the canal as long as there exists the smallest contraction in the urethral canal.

We come now to the consideration of posterior urethritis. In the posterior urethra the changes are more or less similar to those in the anterior urethra. The glands and follicles present the same pathological modifications, and the ducts may likewise become occluded. The mucous membrane is swollen and congested, the verumontanum elevated and softened. The symptomatology differs from the more important annexe which become involved—I mean the prostatic gland, the seminal vesicles, and the neck of the bladder. I will not go into details regarding all these pathological conditions, as they were partly enumerated in the consideration of the anterior urethra. It is enough to state that here, more than in the anterior urethra, epithelial changes, granulations, and cysts are found.

One of the characteristic features of chronic posterior urethritis is the rapid formation and shedding of the epithelial cells. If congested, eroded, or granular patches are present, there will be a constant oversecretion of mucus or mucopus, with exfoliation of epithelium. As to the treatment, here, as in the anterior urethra, the canal must be very carefully explored in order to find out the character and location of the particular lesion or lesions which keep up the discharge—the bougies a bottle to locate the stricture and the urethroscope to determine the character of the lesions. If strictures exist they must be dilated to obliteration. If we find granular patches, they must be treated locally through the urethroscope. There are various instruments in the market, some straight tubes, some curved. The straight tubes are very dangerous, and their use is painful to the patient; and they are therefore condemned by most of the authors. The curved ones, on the other hand, are quite complicated, a fact which makes their use difficult. Through these tubes applications can be made to the diseased parts in the form of nitrate of silver or sulphate of copper. The silver salt can be employed either in solution, on a pledget of cotton, or fused upon the end of a fine metallic probe. An easier method of using nitrate of silver is by instilling the solution through one of the instillators, the Ullman being the best. After making the patient urinate, the canal is washed out with boric acid solution or with plain sterile water; from two to three ounces of sterilized water is instilled into the bladder. The instillator containing the solution is inserted in the canal when we pass the cut off muscle, then the solution is slowly instilled, drop by drop, until
about twenty c. c. have been introduced. On withdrawing the instrument none of the solution should be allowed to come out, as it would then become an anterior urethral instillation.

If we find minute granulations, a good method is the introduction of a large steel sound. In this way we crush the granulations, we empty the follicles which contain pus, produce absorption of the infiltrated tissue, and stimulate the mucous membrane. Irrigations with an antiseptic solution must always follow the introduction of any instrument.

There are chronic cases of urethritis due to a too long and too harsh treatment. In these cases the epithelial surface is abraded, the whole canal is constantly inflamed and raw. Discontinuation of treatment in these cases will often bring about a rapid cure.

I only mention the urethritis in diabetics, tuberculous, gouty, etc. The general condition of these patients must receive appropriate attention and care.

There are some cases of chronic urethritis which cannot be cured, no matter how we treat them. These cases are found in psychopathic patients, and are well named psychopathic urethritis. These patients believe themselves the most unfortunate beings on earth, and go from doctor to doctor, seeking in vain the cure of a condition that does not exist.

I did not want to say anything about the complications of urethritis, but exception must be made regarding prostatitis and vesiculitis. The mucous membrane of the urethra is continued into the ejaculatory canal and the prostatic ducts, so that the inflammation of one is propagated by continuity directly to the others, therefore allow me to say a few words about the treatment of vesiculitis and prostatitis. We know as a fact, that whenever a patient presents himself with a chronic urethritis, treated or mal-treated for a long time, and has still a drop of pus loaded with gonococci, these microbes are usually lodged in the canaliculi of the prostate or of the seminal vesicles. And more important: the retention of the microorganisms in those glandular organs is associated with, and caused by, poor conditions of drainage. Therefore, in order to free these organs of the gonococci, we must fight the retention and make free drainage. This is done by rectal massage of the prostate and the vesicles. The massage must be made carefully and persistently, it must be continued until the foci are emptied, and until the microscope shows only the perfectly transparent normal secretion of the seminal vesicles and prostate. It is a question how often we can safely massage the prostate. The rule is two to three times a week, but this is not sufficient. The massage treatment must be instituted daily without fear, as long as it is made with care. This massage is performed by a downward stripping, and the pressure is regulated by the painful sensations of the patient. At the same time dilatation of the posterior urethra with sounds will facilitate and hasten the cure.

CONCLUSIONS.

In conclusion, I will say, that in order to cure a case of chronic urethritis it is necessary to make a careful investigation in each case, that we may discover the underlying cause, and prescribe the proper treatment. We, more than anybody else, know about patients treated for a long time without success. What is the reason? The general practitioner, unfortunately, immediately after seeing a patient with a discharge, or with some shreds in the urine, makes the diagnoses of urethritis and starts injecting silver salts into the canal. It seems that as soon as one pronounces the word gonorrhoea, the other word, silver salts, appears before his mind. Gonorrhoea means silver salts and nothing else. If we proceed in a systematic way, if we know our anatomy and pathology, if we are familiar with all methods of investigation, and with a judicious use of drugs and apparatuses at our disposal, we should find that there are no incurable cases.

17 Livingstone Place.

THE INTRAVENOUS TREATMENT OF RHEUMATIC FEVER.

By Paul M. Patterson, M. D.,

New York.

House Surgeon, Metropolitan Hospital, Blackwell's Island.

This method of treating rheumatism is the outcome of observations made in the tuberculosis division of the Metropolitan Hospital. When the intravenous injection of Doctor McDuffie's formula of sodium salicylate, guaiacol, and glycérine was given to patients who were suffering also from rheumatism, prompt relief of those symptoms was noticed. (New York Medical Journal, March 15, 1913.) Consequently Doctor Bolten, of the house staff of nineteen hundred and twelve, gave it in a case of acute articular rheumatism and the results were most pleasing.

This method of treatment has been followed in twenty-eight acute cases under our observation, also in several subacute and chronic cases, in one case of gout, and in one of gonorrhæal arthritis, with most gratifying results.

Dr. McDuffie's original formula consisted of:

Sodii salicylatis, . . . gr. xxxviiiss (2.42 grammes);
Guaiacolis, . . . . gr. xiiiss (0.80 grammes);
Glycerini, . . . . . gr. i (3.22 grammes);
Aque destillatæ, q. s. ad . . . 3viiss (22.00 grammes).

This was given intravenously. This was later modified and the following formula used:

Sodii salicylatis, Guaiacolis, . . . . 3â 5xi.ii (41.20 grammes);
Glycerini, . . . . .
Aque destillatæ, q. s. . . . . . . Ovi (2000.00 c. c.).

Of this prescription 75 cubic centimetres (two and one-half ounces) were given together with 125 cubic centimetres of normal saline at a temperature of 100° F.

No preliminary preparation of the patient was made, except the administration of a dose of magnesia sulphate or some saline water, and the patient confined to bed between blankets. The arm was prepared as for an ordinary infusion and the infusion was given under strict aseptic precautions. The mixture was allowed to run into the vein slowly, taking from five to ten minutes for the infusion. Early symptoms were not a feature of the treat-
ment, but in several cases the patients complained of dizziness or sleepiness. This is an indication to stop the infusion, but in no case were these symptoms manifested until at the close of the injection, and in no case was it necessary to discontinue the infusion. In one case, slight delirium was present just before the full amount had been given. This passed away in ten minutes.

It has been asked many times why guaiacol was included in the prescription, and why salicylate was not given alone. The salicylate alone causes vertigo, tinnitus, and embarrassed respiration, which is sometimes so alarming as to prohibit its use entirely. When guaiacol is included this is done away with; it also increases the hemoglobin from five to twenty-five per cent.

As a rule, within thirty minutes to one hour after the injection the patient began to perspire profusely. This continued for from four to ten hours and with it came complete amelioration of all symptoms. The inflammation, swelling, and pain disappeared, and all that remained was the feeling of stiffness of the joints involved. This stiffness gradually disappeared in from one to three days. In two cases with high temperature slight chills were experienced fifteen minutes after the injection, but they were not followed by a rise of temperature nor any bad effects.

The aftertreatment has been routine. Liquid diet was continued for eighteen hours. Hunyadi János, Bokert Spring water, or magnesia sulphate was given every second morning. Sodium salicylate, fifteen grains, and sodium bicarbonate, five grains, were given every three hours for twenty-four hours, and then three times a day.

In the one case of acute gout the results were as satisfactory as in the rheumatic fever, and the case of gonorrheal arthritis was benefited. The swelling, inflammation, and achillodynia disappeared. However, two injections were given four days apart, before the temperature and stiffness were controlled. The temperature did not disappear altogether until the urethral condition was apparently cured. In the chronic cases a second intravenous injection was given four or five days afterward where some benefit was received, but not complete amelioration after the first injection.

The cases treated from the beginning of the attack left the hospital in from six to twelve days apparently cured. Two patients returned to the hospital, one in two weeks and the other after a longer period. Both gave a history of alcoholism and improper care of themselves and no treatment since leaving the hospital. Not a single failure as to relief has been observed, whether this is temporary or permanent remains to be seen. It was quite interesting to see fingers that were stiffened, movable the next day, and very gratifying to hear patients ask to be allowed up when twenty-four hours before they would do anything rather than move.

It is believed where a physician is able to follow up this intravenous injection by proper medication, dietetics, and hygiene, it is far superior to any treatment we have, not excluding the vaccines. For prompt relief, we know of nothing that will equal it.

Metropolitan Hospital, Blackwell’s Island.
in capsule and in proper dose. Even the pain and insomnia of acute rheumatism, migraine, and severe neuralgias have yielded to it in my practice.

But none of these drugs are to be employed for any length of time. Since under the term insomnia are included all grades of loss of the normal amount of sleep, from simple and transient restlessness to total loss of sleep with tossing and delirium seen in many diseases, it is evident that no one remedy or dose will meet all requirements. Each patient must be individualized, and must be treated in accordance with his special and peculiar needs. The various factors entering into the cause of insomnia must be discovered and, if possible, removed.

The treatment of insomnia may be classified under four general heads: Hygienic, including hydrotherapy, dietetic, psychic, and medical. The successful treatment of any case may require any or all of these measures. Under hygienic are included such items as the maintenance of bowel regularity; the avoidance of coffee, tea, and tobacco if the insomnia depends on their use, providing a quiet bedroom with a moderate temperature and fresh air; horseback exercise or a walk or drive for those who are too much indoors and who have need of relaxation before bedtime; the use of hot and cold water as the case may require; massage and electricity. A careful study of each case will dictate the measures to be employed.

Aside from the insomnia of organic disease, a large number of our cases depend on a nervous instability or irritability on nervous exhaustion. These are the cases which above all others try the skill and the patience of the physician. It is evident folly to feed a hysterical or a neurasthenic with bromides, chloral, and morphone; but the cruel folly is committed daily.

My watchword is, “Avoid narcotics!” Place your reliance on rational general treatment, on hydrotherapy, on suggestive therapeutics. Many of these patients fail to sleep because of what may be termed an insomnophobia—the fear of sleeping—the mere overanxiety to get to sleep. Here it is necessary to gain the confidence of the patient, to explain the harmlessness of a moderate loss of sleep. Rid his mind of fears, obsessions, and phobias; give assurance and reassurance. A warm bath at bed time will often secure a restful night. If drugs are deemed necessary, their suggestive action must be made use of to enhance and to prolong their effect. But drugs are only palliative. They cannot cure. They should never be used for any length of time, and as it is especially difficult to prevent these patients from becoming drug habituates, it is usually wiser to dispense entirely with their use.

Often a warm bath at bed time, with brisk friction and perhaps a cold cloth on the head, will do what many drugs have failed to accomplish. The cold bath and hot or cold applications to the head or the back have their indications, as has judicious electrical treatment.

For those of sedentary habits who are troubled with cold feet, a hot foot bath will often induce sleep. It may be that a light and easily digested evening meal will make the difference between sleeplessness and refreshing slumber.

In those who are exhausted by mental concentration and business cares, we must secure thorough relaxation during the evening hours. Some diverting entertainment, music, a drive or horseback riding may prove valuable adjuncts. If these means and the employment of hydrotherapeutic measures fail after a fair trial, a vacation and a complete rest should be obtained. It is unwise to expect narcotic drugs to replace physical and mental energy and psychic power which are being exhausted more rapidly than the bodily economy can replace it.

If drugs are necessary, selection may be made of any of the simple hypnotics in proper doses to meet the individual requirements. The most useful to me have been the bromides, chloral, chloretone, and paraldehyde. Sulphonal and trional are good, but are objectionable because of their bulk and the difficulty of swallowing them. Moreover, sulphonal is toxic in large and continued doses, somewhat cumulative in action, and may cause hematorphyrinuria. Combined small doses of veronal and codeine have afforded me good results. But rest, tonics, and a hygienic mode of life are more potent to improve the morale and the nervous and mental equilibrium of our nervous patients.

The insomnia of cardiac incompetency, due to passive hyperemia of the brain, is often associated with general nervous irritability and must be treated with consideration for the weakened heart muscle. The rational treatment consists in the judicious administration of cardiac tonics, digitalis, strophanthus, strychnine, etc., to overcome the cerebral hyperemia (or anemia). Chloral as a hypnotic is too depressant in these cases, in that it causes a paresis of the vasomotor centres and a congestion of the peripheral organs, including the brain itself—acting thus much like chloroform.

This is true to some extent also of opium and its alkaloids in large doses; but a hypodermic injection of a small dose of morphine, perhaps given in conjunction with the proper heart stimulant, often acts like magic. The bromides are also useful. They quiet the sensibility of the whole nervous system, especially of the special senses and of the peripheral nerves, so that external influences cannot stimulate an over irritable brain. But potassium bromide must be employed with care in valvular lesions, as large doses weaken the heart and reduce the blood pressure. My preference is for the bromide of sodium, as it causes less general depression and less gastric irritation. It is best given in milk, in divided doses, say fifteen to twenty grains, three hours before, and just at bed time. In women Fowler’s solution should be combined with it to prevent acne. Paraldehyde and chloralamide are also efficacious. If the temperature is subnormal and the vital forces are low, hot applications to the head are often of service in securing sleep.

The insomnia of chronic parenchymatous nephritis is usually accompanied by headache, and depends on an uremic or other intoxication of the nervous system. It should, therefore, be attacked by eliminating the toxins. Stimulate the excretory organs by using purgatives, diuretics, diaphoretics, hot packs, and by securing the ingestion of plenty of fluids. Of drugs, chloral hydrate has served me
well. Morphine, cautiously, and in small doses, may be given; nitroglycerin and erythrol tetrachlorate are often helpful by acting to reduce the high blood pressure.

In severe typhoid fever, insomnia and restlessness may exhaust the vital forces by continued nervous and muscular activity. Hence it may be necessary to secure sleep in order to save the life of our patient. For this purpose the bath is a great blessing. The temperature of the water must be gauged by the body temperature. Valerian is a useful adjunct. In severe cases, however, where a night of refreshing sleep may turn the scales from death to life, we must often have recourse to opium or some of its congeners. If diarrhea is marked, powdered opium may be given. If constipation is present, I prefer codeine phosphate, heroin hydrochloride, or hyoscine by hypodermic injection—or morphine may be given, best with 1/100 grain of nitroglycerin to prevent secondary nausea and depression. In milder cases the bromides and chloral in small doses may be given, either by mouth, or per rectum with starch water.

The insomnia of cystitis dependent on frequent urination and tenesmus has yielded for me to full doses of hyoscyamus (or belladonna) together with codeine.

The insomnia of cerebral syphilis should be attacked by the prompt employment of efficient antisypilitic treatment—in other words, salvarsan or neosalvarsan. Temporarily, employment may be made of any of the hypnotics or narcotics, including morphine. The latter is frequently necessary because of the severe headache which often accompanies the insomnia.

The insomnia of rheumatism may require morphine in addition to the pure hypnotics, but the salicylates and codeine are the ultimate cure.

The insomnia of such diseases as influenza, pleurisy, pneumonia, tuberculosis, asthma, and angina pectoris, which is dependent partly on pain and partly on fever, cough, digestive disturbances, or dyspepsia must often be removed with the aid of opium or its alkaloids. Dover’s powder in proper dose is my preference in the early stages. Later morphine is useful, but constipating, and I prefer codeine phosphate up to one grain hypodermically, or heroin hydrochloride, from 1/24 to 1/12 grain, repeated if needed. The latter has been especially helpful where pain and cough are both factors in the insomnia.

Inasmuch as pneumonia is such a fatal disease, the insomnia and restlessness which so often accompany it and exhaust the patient deserve a special word. Since the insomnia is dependent on the various and varying factors—pain, cough, cerebral hyperemia, and intoxication—these items must all be considered in its treatment. In the beginning, calomel, followed by a brisk saline cathartic or a stimulating enema, is indicated to aid in the elimination of the toxins and to lower the arterial tension. If the condition of the heart allows, chloral and the bromides may be used with care. Trional in ten grain doses may be given, and repeated after one or two hours if needed. Always the use of hot or cold application and baths is to be commended. If in spite of these measures the restlessness and insomnia continue, it is my custom to administer codeine or heroin hypodermically. Morphine in small or ascending doses may be needed, accompanied by whatever heart stimulants are indicated. The rule must be always to conserve and increase the vital resistance, and unquestionably by the timely employment of the proper remedy we can often prevent exhaustion and save life. This must be the test of any means employed to combat insomnia.

To recapitulate: Treat the underlying disease, not the symptom insomnia. Beware of the narcotics in protracted acute and in chronic disease, for fear of chaining your patient to a soul destroying habit! In fatal illness, in cancer, and in the terminal stages of tuberculosis, give them if necessary to secure comfort and perhaps even to promote euthanasia.

Dr. Edward H. Bedrossian, of Philadelphia, Pa., says:

As insomnia is nothing but a symptom, rational treatment will consist in an attempt to remove the cause and establish conditions that are found in normal sleep.

The treatment of insomnia in all cases where the organs and tissues are intact and the cause lies in an accidental mental stimulation, nervous irritability, exhaustion, worry, overwork, etc., should be carried on with a view of inducing natural sleep, and in every case drugs should be saved until other measures have been tried and failed. The measures to be considered are:

Diet. This should be liberal and sufficient to keep up the bodily weight, but easily digestible and nourishing. Animal proteins should be reduced to a minimum and the heaviest meal should be taken at noon. Supper should consist of eggs and milk. A glass of hot milk at bedtime is often a good soporific. A strict milk diet is very desirable, as it does not give rise to large amounts of waste material in the system. Stimulants, tea, coffee, alcohol, and sweets must be forbidden. Tobacco may be allowed in moderation.

General hygienic measures. These should receive due attention. The bowels must be kept well open by a vegetable laxative. A well ventilated and quiet room, free of cumbersome furniture; a comfortable bed with dry, clean, and warm bed clothing; an hour in the fresh air before retiring; and a sufficient amount of rest, etc., should be considered necessary means to lessen nervous irritability and induce natural sleep.

Hydrotherapy. This is one of our most reliable and powerful measures. It relieves cerebral and visceral congestion, improves the peripheral circulation, and relaxes the nerves. It may be given as a lukewarm bath of half an hour’s duration before retiring, and repeated if the patient awakens during the night. If this fails a shower bath, either hot or cold, for half a minute, the patient being then wrapped in a sheet wrung out of tepid water for one minute, will often succeed in inducing sleep. A cold, wet towel wrapped around the neck, the feet bathed for fifteen minutes in hot water, local packs around the legs or abdomen, a warm body bath with cold compresses to the head, and
many of the other hydrotherapeutic measures may be applied with gratifying results.

Massage and passive movements. These applied as such, or in conjunction with hydrotherapy, are a very valuable means to relieve fatigue, exhaustion, and congestive disturbances. Massage may be applied locally or generally by a skilful operator or by an ordinary electric hand motor made for the purpose, the use of which can easily be taught to one of the family or to an intelligent attendant.

Electricity. Applied for the treatment of insomnia, electricity has the same ends in view as massage and passive movements. It has not the same influence on the circulatory system as these agents, but in addition to the shock and stimulus to the nervous mechanism, it has such a strong suggestive action on the patient that in a number of cases it has proved a very suitable remedy. It may be used in the form of the galvanic, faradic, static, or high frequency current.

Psychotherapy. This is practised by every man consciously or unconsciously. A sincere and scientific mind will make use of it on a rational basis for cases of insomnia when the patient is suffering from a great calamity, misfortune, sorrow, persistent mental preoccupations and obsessions. The tactful and judicious physician will do a great deal by mental gymnastics and instruction to help the patient acquire full control over his thoughts, and overcome the distressing idea in his mind.

Medicotherapy. In the use of drugs for insomnia we should always guard against habit formation and against the untoward effects of the drugs used. Our choice will be better if confined to the few and harmless remedies to be found in the long list of sedatives, hypnotics, and narcotics.

In sleeplessness from anxiety, sodium or potassium bromide given in ten grain doses, or combined with five grains of chloral hydrate or with five minims of the tincture of cannabis indica; cannabin tannate (unofficial), in five grain doses, is very valuable. The action of the bromides is due to the bromion ion, which reduces the irritability of the motor areas in the brain and retards the reflexes by interrupting the passage of impulses from the sensory to the motor cells of the cord. For continued use its cumulative action has to be remembered and any evidence of bromism promptly recognized.

In sleeplessness due to abnormal activity of the motor areas, and in the insanities, hyoscine hydrobromide is of great service. In doses of from 1/150 to 1/120 grain it acts as a depressant to the central nervous system, and produces light but refreshing sleep, similar to natural sleep.

In cases of nervous exhaustion, cannabis indica is probably the best drug to use. It is not very reliable, but in therapeutic doses it has no untoward effects, and it may be used when the other hypnotics are contraindicated.

In cases of excitement the chloral group of hypnotics are the best. These drugs produce sleep by dulling the perceptions, and are used quite extensively with success; but tolerance is soon established and the chlorine ion found in chloral hydrate and in some of its congeners contraindicates their use in cardiac diseases. Paraldehyde for its very unpleasant odor, and sulphonal for the resulting hematoporphyrinuria in long continued use, fall short of being ideal drugs. Of chloralamide, amyline hydrate, urethane, trional, medinal, tetronal, etc., probably veronal is the best. It is not as strong as chloral or sulphonal, but it is devoid of any action except on the nervous system, and in five to ten grain doses given in hot milk it induces natural sleep without any subsequent depression.

In cases of sleeplessness due to pain not relieved by local or other palliative measures, morphine is indicated. Opium and its preparations have an analgesic action that is not shared by the methane series. When there is much excitement with pain, chloral and opium may be administered together in much smaller doses than when prescribed separately. Opium is an invaluable drug, and many occasions will arise in a number of diseases when it will be impossible to do without it; but it should be used with great caution on account of the appalling danger of habit formation. It may be administered in the form of powder, extract, tincture, pill, or one of the alkaloids by mouth: the suppository by the rectum; the alkaloids and some of the newer preparations by hypodermic injections.

In insomnia arising from any disease the primary treatment is that of the disease, accompanied by any of these measures, as indicated.

(To be continued.)

Therapeutic Notes.

Treatment of Gonococcal Vaginitis.—H. Roulland, in Semaine gynécologique for February, 1913, states that in the acute period of this affection, absolute rest in bed for a few days should be advised. Vaginal irrigations three times daily with a decoction of poppy or marshmallow, at a maximal temperature of from 102.2° to 104° F. (39° to 40° C.), may be ordered. These may be alternated with a 0.5 per cent. solution of sodium bicarbonate. If the use of a glass cannula proves too painful, a soft rubber tube should be employed. As soon as the pain has been reduced by these irrigations, a one in 4,000 solution of potassium permanganate should be substituted. At night a simple glycercin suppository, or one medicated with ichthyol, may be left well up in the vagina.

To assuage the marked local pain and burning, the following suppository may be used:

R Morphin hydrochlorid. gr. 1/2 (001 grammes).
Extracti belladonnae foliorum, gr. 1/2 (003 grammes).
Olei theobromatis, gr. xlv (3 grammes).
Fiat suppositorium No. 1.

An enema consisting of the following combination might also be ordered:

R Antipyrine, gr. xv (1 grammes).
Tinctura opii, gtt. xv; Aqua bullite, 3v (150 grammes).

Misc.

Copious enemas of water, as well as laxatives, likewise afford considerable relief in these cases. The diet should be light, and fluids freely ingested.

Where the affection is of a subacute type, vaginal irrigations with a one in 2,000 solution of potassium
permananate are alone indicated. In the intervals between injections the walls of the canal should be kept apart by means of a gauze tampon upon which some soothing yet stimulating ointment such as the following, advised by Dolériés, should be spread:

R. Petrolatii, .................. $\frac{1}{2}$ xlv (10 grammes);
Zinci oxidi, .................. $\frac{1}{2}$ iii (7 grammes);
Camphora, .................. gr. xlv (3 grammes);
Resorcini, .................. gr. xv (1 gramme).
M. Ft. unguentum.

The amount of gauze should be just sufficient to keep the walls of the vagina apart, and not enough to produce pressure.

When the local redness and burning have distinctly lessened the mucous membrane, including all its folds, should be painted every three days, using aBBB B, with a one in 50 or a five in 50 solution of silver nitrate. After this tampons of sterile cotton impregnated with a five per cent. suspension of iodine form in glycerin may be applied to the uterine cervix. If the silver nitrate gives rise to too much pain, a solution of one of the organic silver salts or a colloidal silver preparation may be used. The following preparation may also be employed:

R. Acidi acetici, .................. gr. lxxxv (5 grammes);
Glycerini, .................. $\frac{1}{2}$ iii (100 grammes).
Fiat soluto.

When vaginitis becomes chronic it is localized at the cervix and vulva. Metritis and vulvitis are therefore the conditions requiring treatment. The vulva and vagina should be repeatedly washed with soap and water morning and evening. Applications of silver nitrate, colloidal silver, or concentrated permanganate solutions are indicated and will not fail to yield beneficial results.

Treatment of Phenol Gangrene.—H. Rozies, in Monde médical for June 15, 1913, writes concerning a patient whose finger, becoming the seat of a felon, had been treated, ten days previously, by incision and the application of an ointment containing phenol. Although healing had promptly followed, the finger had become grayish and insensitive, then acutely painful, and when first seen, its terminal phalanx and a portion of the second appeared shrunken and grayish blue. The nail was gone, sensation lost, and at the second phalanx there was an irregular tender zone, devoid of inflammatory reaction.

The treatment adopted consisted of salt baths and applications of hot air, the latter being supplied by an apparatus consisting of a blower heated by an alcohol lamp. A jet of hot air was directed daily upon the gangrenous tissues from a distance of five centimetres, then more diffusely, over the neighboring painful tissues, from a distance of ten centimetres. Promptly, after the first few sittings, the pain left and the affected area became more sharply limited. The normal color of the member returned and circulatory activity in it was increased. The dead portions of tissue separated, leaving an aseptic ulcerated surface over which, under continued hot air treatment, epithelial growth rapidly took place.

The treatment here somewhat thinner than before. The treatment had, however, clearly prevented bacterial pullulation in the part, relieved pain, and accelerated repair. The author suggests that in the small proportion of cases of phenol gangrene of the moist type this treatment would also prove serviceable.

Sodium Citrate in the Treatment of Merycism.—G. Vario, in Bulletin et Mémoires de la Société médicale des Hôpitaux de Paris, May 1, 1913, reports the case of a girl sixteen years old who, since the age of nine, had been troubled with regurgitation of food, generally about ten minutes after meals, though occasionally during them, or an hour later. Special diet brought only temporary improvement, and bromides were without effect. Upon a trial of sodium citrate, however, in daily doses at first of four grammes (1 drachm), taken in divided amounts before meals, and later of six grammes (1 1/2 drachms), brought about a marked improvement in the trouble, the regurgitated material being merely watery, and much less in amount. Temporary discontinuance of the drug was followed by a reappearance of the previous abundant regurgitations. Under continuous medication the patient gained in weight. It was found that the taking of a glass of water, to which the juice of half a lemon and a teaspoonful of sodium bicarbonate had been added, would exert the same sedative action on the stomach as the sodium citrate.

Treatment of Otitis Externa.—R. M. Nelson, in the Journal of the American Medical Association for March 8, 1913, states that he has found a mixture containing five per cent. each of phenol and ichthiol in glycerin remarkably efficacious in the treatment of otitis externa diffusa, myringitis, otitis externa circumscripta ("furuncle of the canal"), and, in connection with other treatment, as good as any ear drops in acute otitis media. The mixture proved especially effective in otitis externa caused by and complicating chronic supplicative otitis media, and in general, was particularly valuable where ordinary methods, after careful trial, had failed to give relief. It was applied on cotton tampons.

Treatment of Pharyngitis.—Nouveaux Remèdes for March 24, 1913, suggests the following oily solution, to be applied to the throat in pharyngitis:

R. Phenylis salicylatis, .................. gr. xlv (3 grammes);
Petrolati liquidi, .................. $\frac{1}{2}$ x (40 grammes).

Solve.

The following is for inhalation:

R. Mentholis, .................. $\frac{1}{2}$ iii (2 grammes);
Tinctura benzoini compositive, .................. $\frac{1}{2}$ iii (100 grammes).
Tinctura eucalypti, ..................

M. Sig.: One teaspoonful to be added to a pint of boiling water and the vapor inhaled.

Treatment of Pyrosis.—Peter, in Paris médical for May 17, 1913, is credited with the following combination, to be administered to patients in whom a milk diet provokes acid regurgitations:

R. Soddii bicarbonatis, .................. gr. xl (25 grammes);
Curzae preparata, .................. gr. xv (1 gramme);
Extraciucis vomicae, .................. gr. iss (0.1 gramme).
Misce et divide in cachetas No. x.

AUTGENOUS VACCINE IN ACUTE
ANKYLOSTOMIASIS.

Several facts relative to ankylostomiasis suggest that the hookworm itself is not always exclusively responsible for the symptoms observed in this form of parasitic invasion. Thus, it is known that in some cases fever continues long after specific treatment has eliminated the parasites. Again, different types of fever have been observed by Castellani in hookworm infection, suggesting that more than one pathogenic agent is operative. That Padua and others have found the intestinal putrefactive processes very marked in ankylostomiasis leads Captain R. G. Archibald, of the British Army (Journal of Tropical Medicine and Hygiene, September 1, 1913) to ascribe the clinical evidences of toxemia, unaccounted for by the hookworm, to the absorption of the poisonous products of certain intestinal bacteria. This view is confirmed by a case he reports, the patient suffering from continuous fever, anemia, headache, anorexia, vertigo, constipation, and evidences of severe toxemia, in which, after eucalyptus oil and chloroform in large doses had failed to bring relief, death being apparently imminent, the administration of an autogenous vaccine prepared from a coliform organism isolated from the stools caused immediate and striking improvement. The spleen and liver, previously en-

larged, diminished in size, weight was gained rapidly, and soon after the patient was discharged. In two other acute toxic cases vaccine therapy was likewise employed, with very gratifying results. While the number of cases is small, there seems to be no reason for denying their probative value, and one may look with favor upon the author’s recommendation, in certain cases of severe and intractable ankylostomiasis, to employ autogenous vaccines of any suspicious intestinal organism in conjunction with or even before—to lessen the danger from toxic effects—the specific antihelmintic measures.

TRAINING FOR OPHTHALMIC PRACTICE.

Many good ideas were brought out in the proceedings of the Conference of Teachers of Ophthalmology held last June in Minneapolis, as reported in the Ophthalmic Record for August, two of which seem to us to deserve particular mention. One, that some provision should be made for a place where a complete training in ophthalmology can be acquired; the other, that the relations of the eye to general medicine should be made so prominent in the teaching of the undergraduate student, that he will become a general practitioner with a clear understanding of these relations.

We believe that the first is in process of evolution. Doctor Jackson showed from the statements of 250 ophthalmologists in active practice in America that they had spent an average of three years, some of them five and seven years, in a more or less desultory preparation, while none of them had been able to secure a complete, well rounded education in the subject in that time. It is hard to believe that men are willing to sacrifice so much time as interns in hospitals, as assistants in private practice, and in attendance on clinics in various parts of the world, and yet would be unwilling to devote it to systematic study at some place where they could attain much better the aim they have in view. It would seem as though there were an opportunity for one of our best postgraduate schools to inaugurate a three years course of systematic instruction in ophthalmology under the direction of one competent head. One of the difficulties suggested is the demand for a short course on the part of men who desire an easy road to the emoluments of the specialist, and the doubt that many of them will voluntarily choose the long one. After a course of training lasting three months or so few of the students know any more about the eye than every general practitioner should, their skill is conspicuously absent, at least in the eyes of the expert, and their ability to fit glasses is scarcely superior to
that of the optometrist. It seems probable to us that when the general practitioner knows as much of the eye as he does of any other of the organs of the body there will be a lessened demand for short courses in special training from those who wish to qualify as specialists.

This brings us to the second idea, that the relations of the eye to general practice should be made clear to the undergraduate student. But the curriculum is already overloaded, the teachers of ophthalmology do their best in the few hours at their disposal, and these hours cannot be lengthened without increasing the length of the course of study. Very true, yet something might perhaps be accomplished. The student is taught in the classes on general medicine to observe the pupils in a case of suspected tabes, and is advised to have an ophthalmoscopic examination made in search of optic atrophy. The prognostic value of the findings of such an examination in cases of renal disease is also mentioned. Would not the intimate relation of the conditions in the eye to the general disease be made more real to him if his teacher in clinical medicine used and had him use the ophthalmoscope for diagnostic purposes in the examination of the many diseases in which intraocular symptoms coexist? These teachers now call attention to the iritis complicating syphilis and rheumatism; could they not at the same time point out the symptoms by which they recognize it to be an iritis, and not a conjunctivitis, or a glaucoma? Suppose this does trench on the domain of the ophthalmologist, he trenches quite as much on that of the gynecologist, and of other specialists. We need many, many more general practitioners who are able to make an intelligent examination of the eye, to recognize lesions within it, and to trace the connection between them and the other symptoms presented by the patient, who would think to use the ophthalmoscope in cases of unexplained persistent vomiting, of doubtful symptoms referable to the central nervous system—in short, in all obscure cases. It seems to us that much would be gained in every way if students were to see the ophthalmoscope frequently used by their teachers of clinical medicine as an instrument of diagnosis, without laying any additional burden on the curriculum.

THE HEART IN SYPHILIS.

Though as long ago as 1906 Buschke and Fisher demonstrated the presence of the spirochetes in the heart muscle in cases even in the early secondary stage, most recent writers appear to agree with the older authorities as to the infrequency of cardiac involvement in syphilis. The only reference which von Zeissl makes to this is to state that callous inflammation and gummatous develop in the heart in very rare instances; callous inflammations affecting one or all of the layers of the cardiac muscle, while gumma almost always attacks the myocardium. A prominent American authority, Otis, made no mention whatever of the heart in his Clinical Lectures on the Physiological Pathology and Treatment of Syphilis, published in 1881. After quoting the findings of Cornil and Ranvier, Hueber, and Edes, Otis says: “Thus it will be seen that the degeneration of arteries from syphilitic influences consists, according to recent eminent authorities, in an antecedent accumulation of cells and the growth of new fibrous tissues at the points of degeneration.” Ziegler asserts that there is nothing specific in the histological process, though it may be said that in the ordinary arteritis of small vessels no such enormous accumulation of cellular infiltration occurs as in syphilitic inflammation. While syphilis of the heart itself has been considered so rare, Harlow Brooks (American Journal of the Medical Sciences for October, 1913) states that it has a specific affinity to attack the coronary arteries. He believes that the apparent rarity of cardiac involvement is probably due to the relative infrequency with which true gumma of the heart is found at necropsy.

Doctor Brooks’s investigations have led him to conclude that aortic involvement of the heart is much more serious in its direct effects, as well as much more frequent, than has generally been supposed. He finds that in his post mortem series death occurs in no less than sixty-six per cent, of his syphilitic cases as a result of or with serious circulatory disease apparently of specific origin. The myocardium was found diseased to a serious extent in forty-four of the fifty cases, but true cardiac gumma was present in only five instances. One patient died before the secondary rash had fully appeared, due to a minute perforation of the wall of the aorta. A pronounced acute arteritis and periarteritis was found throughout the myocardium, particularly involving the vasa vasorum of the aorta. In twenty-eight cases opacities composed of mingled fibrous and endothelial hyperplasia were found in the visceral pericardium, and in thirty-five, disease of the coronary arteries was present to a greater relative degree than the general arteritis. For some time past Doctor Brooks’s clinical studies have been largely directed toward an attempt to answer the questions, When do these lesions occur? Do they produce effects which are clinically recognizable? Can they be prevented? Can they be cured? As to the time of occurrence, if, as he believes he has demonstrated, these specific effects are
inflammatory changes develop first in and about the arterioles of the heart muscle, it is plain that their onset should occur among the earliest of all visceral disease in this infection. While in both early and late cases irregularity of heart action is the most characteristic and frequent clinical manifestation, in general the signs and symptoms are those of cardiac disorder; the history, general aspects, and the Wassermann reaction may indicate the true etiology. Good results—cures in many instances—will follow appropriate antisyphilitic therapy. Patients in the active and progressive periods of the secondary stage who have been promptly and thoroughly treated by modern methods have thus far shown no recognizable cardiac complications.

OPERATIONS AND METASTASIS IN CARCINOMA.

For many years there has been a feeling among surgeons that mechanical disturbances of malignant tumors are dangerous, on account of the increased liability to metastases, or secondary growths, incident thereto. This view has been based, in the past, on purely clinical observations; recent labors along experimental lines with mouse cancer have tended to strengthen it.

From the surgeon’s standpoint this is an exceedingly important matter. What he wishes to know is, whether the growth of secondary masses, in patients in whom metastasis has already occurred, will be accelerated by the removal of the primary tumor, whether life will be shortened or prolonged, and whether the procedures followed in the course of physical examinations or surgical operations increase or diminish the frequency of, or liability to, metastases.

Clunet found that of one hundred and forty-five mice which succumbed to implants of a certain strain of tumor, none showed metastases visible to the naked eye. On the other hand, of eleven mice which were operated on for the removal of nodules of this tumor, five showed metastases. Another series of experiments gave very similar results and Clunet thus concluded that metastases were more frequent in those mice which showed recurrent tumors for a considerable period following operation.

More recently Tyzzer in this country reports experiments on cancer mice along these same lines. He comes to two interesting conclusions. He finds that operations, incomplete but involving the incision of implanted tumors, do not increase the incidence of metastases. The secondary tumors that are present, however, grow more rapidly. This is due either to an increase in the amount of food material made available by the removal of a large mass of tumor tissue elsewhere, or to the elimination of the element of cachexia, and improvement of the physical condition which almost invariably occurs. It was also noted that metastases may be produced artificially by the manipulation and massage of the implanted tumor. This is accomplished as readily during the early development of the tumor, as in the period in which metastasis naturally occurs.

It is therefore evident that there should be as little mechanical disturbance as possible, before or during an operation.

THE PHARMACOLOGY OF THE BODY TEMPERATURE.

In a brief paper, Henry G. Barbour records in the British Medical Journal some very interesting observations made on the direct influence of drugs and temperature changes upon the region of the brain in which the thermoregulatory centres are supposed to lie. Puncture of the corpus striatum, under aseptic precautions, was made with a double metal tube, closed at its distal end, which was fixed in situ so as to allow the animal to recover. By passage of water through this tube the influence of heat and cold could be determined. It was found that when the temperature in the brain at this point was raised to 42° C, there was an immediate fall of the rectal temperature of the animal. “Heat centrally applied acts, therefore, as an antipyreic; upon this fact undoubtedly depends the automaticity of the temperature centres: the overheated blood of the fever patient tending by its central depressing action to keep the body temperature from going still higher.” Reduction of the local temperature to 33° C. has a diametrically opposite effect. Direct local application of solutions of a number of drugs to this area through a puncture was tried, and the results seem to confirm the central site of the action of these drugs in their influence on body temperature. Choral, antipyrine, quinine, and epinephrin reduce the temperature, as would be expected, while caffeine and betetrahydroaphylamine raise it. By decerebration, partial or complete, it was possible to prove that antipyrine actually causes an increased heat production, which, however, under normal conditions of heat control is overbalanced by heat dissipation.

RECURRANCE AND REINFECTION AFTER SALVARSAN TREATMENT OF RECENT SYPHILIS.

Paul Ravaut, in the Presse médicale of September 13, 1913, cites cases and adduces arguments to show that in patients in the earliest period of syphilis treated with salvarsan, there may appear, a few months later, a recurrence absolutely identical in its manifestations with the original infection, viz., showing a chancre with spirochetes, followed by enlargement of the lymphatics and the usual phenomena of the secondary stage. In a case which he reports, the treatment had consisted of one intra-
venous injection of 0.6 gramme of salvarsan and four intravenous injections of mercury cyanide. In the five months' interval between this admittedly insufficient treatment and the appearance of the second chancre, induration at the site of the first chancre had in part persisted and the glands had remained tender. In nearly all cases reported as recurrences, only relatively small amounts of salvarsan had been given—amounts manifestly insufficient to eradicate syphilis. It is becoming increasingly apparent, moreover, that numerous injections of salvarsan must be given if permanent results are to be obtained. Cases of recurrence such as that already mentioned are believed by Ravaut to result from an excessive local reaction in the site of the initial lesion at the time of the first injections, whereby the spirochetes become shut off from access to the circulation and remain dormant until after treatment is discontinued, recurrence then taking place. While, therefore, in the presence of a chancre, energetic treatment should be given in the hope of sterilizing the organism, in the secondary stage, the treatment should be milder, in order not to cause reactions at the various foci of distribution of the spirochetes. A series of few often ascending doses of salvarsan should be given, followed by a course of mercury, and this, in turn, if necessary, by another series of neosalvarsan injections. The treatment should be continued as long as recognizable foci of disease persist, either by clinical examination or laboratory tests, including the Wassermann and those relating to the cerebrospinal fluid.

INCIDENCE OF INHERITED SYPHILIS IN CONGENITAL MENTAL DEFFICIENCY.

J. Leslie Gordon's observations in the Lancet for September 20th were made upon 400 patients. The Wassermann reaction was the evidence most relied upon. Of the total number, sixty-six, or 16.5 per cent., gave a positive reaction. From three to ten years of age is the time when the greatest number of positive results is found, and the frequency seems to fall decidedly with advancing age. In only eleven of the sixty-six positive cases could stigmata of syphilis be discovered, while among the negative cases sixteen showed some stigmata usually deemed characteristic of syphilis.

Ohio Valley Medical Association.—The fifteenth annual meeting of this association will be held in Evansville, Ind., on Wednesday and Thursday, November 5th and 6th. An excellent programme has been arranged and the meetings give promise of being of great interest to the members. Dr. Benjamin L. W. Floyd, of Evansville, is secretary, and will be glad to furnish complete programmes upon request.

Rat Plague at Seattle.—Seven plague infected rats were found at Seattle, Wash., between September 30 and October 18, 1913. These rats were found along the water front. The municipal health department is actively engaged in the trapping and poisoning of rats and the rat proofing of buildings in the vicinity in which the infected rodents were found. Officers of the United States Public Health Service have charge of the inspection and disinfection of arriving and departing vessels to prevent the spread of the disease by ships.

Operative Clinics at Fordham Hospital.—Announcement is made by the house surgeon of Fordham Hospital, New York, that during the months of October, November, and December, Dr. Alexander Nicoll, attending surgeon at the institution, will hold operative clinics every Saturday afternoon beginning at 2:15 o'clock. Other operating days are Tuesdays and Thursdays, beginning at 2:15 p. m. The medical profession is invited to attend these clinics.

New Department Opened at Jefferson Hospital.—The trustees of the Jefferson Medical College, Philadelphia, announce that the Abraham Jacobi ward for diseases of the chest is ready for occupancy. This new department was made possible by the purchase of the buildings formerly occupied by the Phipps Institute in Pine Street, which have been completely renovated and modernized and every facility afforded for the efficient care of patients suffering from diseases of the chest.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, November 2d, Philadelphia Clinical Association and the Academy of Surgery; Tuesday, November 4th, Wills Hospital Obstetrical and Gynecologic Society and the Medical Examiners' Association; Wednesday, November 5th, Physicians' Motor Club, directors, and the College of Physicians; Thursday, November 6th, Obstetrical Society; Friday, November 7th, Kutztown Branch of the County Society and the Southeast Branch of the County Society.

New Dispensary of the Hospital for Deformities and Joint Diseases.—The board of directors of the Hospital for Deformities and Joint Diseases, New York, have issued invitations to the opening of a new dispensary at 41 and 43 East One Hundred and Twenty-third Street, on Tuesday, November 4, 1913, at 3 o'clock p. m. Addresses will be made by Emanuel M. Griffen, president, Dr. Abraham Jacobi, president, Judge Julius M. Mayer, Dr. Reginald H. Sayre, Felix M. Warburg, and the Rev. Stephen S. Wise.

Red Cross Seals in Great Demand.—The State Charities Aid Association, which will receive the sale of the Red Cross seals in New York State, outside of New York city, states that present indications point to one of the most successful campaigns yet conducted. Hundreds of agents have been appointed, and it is expected that before December 1st an army of 15,000 workers will be pushing the sale of the Red Cross seals. It is the aim of the association to raise $100,000 by the sale of seals between Thanksgiving Day and Christmas Day.

Smallpox in Connecticut.—Acting Assistant Surgeon Stanton, of the United States Public Health Service, reported on October 21st the occurrence of one case of smallpox at Montville, and at the time the report was submitted eight cases were under observation in that town. According to press dispatches the disease exists in a number of mills and factories on the eastern border of the State, the situation being most serious in Danielson, where there are about fifty cases. There have been no deaths from the disease so far. The most rigid quarantine has been established, and as the disease is of a mild type, it is expected that the outbreak will soon be under control.

Four Million Dollar Gift to Cornell University Medical College.—A gift of approximately $4,000,000 to the Cornell University Medical College in this city was announced at Ithaca, N. Y., on Thursday, October 24th, on behalf of the board of trustees. It is understood that the gift, the largest in the history of the university, was presented by Colonel Oliver H. Payne, of New York, who, prior to that, gave a large sum for the establishment of the branch of the Cornell Medical College in New York City. The interest from the gift will give the medical college an annual income of $200,000.

Fortieth Anniversary of the New York Laryngological Society.—The New York Laryngological Society, which was founded in 1874, celebrated its fortieth anniversary of its organization during the latter part of the month. The event is especially interesting, from the fact that this society was the first of its kind to be established, the earliest to follow its example, either in Great Britain, or on the Continent, having been founded ten years later. Twenty-five years ago the society was merged into the Academy of Medicine, becoming the Section in Laryngology and Rhinology. A formal meeting at the Academy of Medicine has been arranged at which addresses will be delivered and a bronze tablet and other memorials commemorating the occasion will be presented.
Admission of Tuberculosis Patients to Sea View Hospital.—On or about November 1, 1913, tuberculosis patients will be admitted to the Sea View Hospital of the Department of Public Charities. Fifty men and fifty women who may be desired are under terms of the hospital are desired who have been found to be unsuitable for Ray Brook or Otisville, but for whom favorable results may be expected, with proper treatment. As soon as possible it is desirable for those patients to be made available. New tuberculosis clinics of the department will be notified to recommend patients for admission. Recommendations will be made to, and admission cards issued by, the Hospital Admission Bureau, 426 First Avenue, Manhattan, in the manner as for admission of patients to other city hospitals.

Philadelphia Medical Club.—At a regular meeting of the Medical Club, held on Friday evening, October 17th, the following nominations for officers were made: For president, Dr. Francis X. Dercum; Dr. Samuel D. Risley, and Dr. Wilmer Kruzen; for first vice-president, Dr. McCluny; for president, Dr. John W. West; for secretary, Dr. William S. Wray; for treasurer, Dr. Lewis H. Adler, Jr.; for governor, Dr. L. Webster Fox and Dr. Clarence F. Franklin; for directors, Dr. Louis A. Houston, Dr. James H. Hughes, Dr. Frank Chandler, Dr. F. Hurst Maier, Dr. Rae S. Dorsett, Dr. Paul J. Sartain, Dr. Henry F. Freund, Dr. Alexander MacAlister, Dr. Edward Horgan, Dr. Matthew Woods, Dr. Harry H. Whitman, Dr. Herbert B. Carpenter, and Dr. Henry V. Acheson. The address of the evening was delivered by President Hibben, of Princeton University, who dwelt on the nonprofessional factors which are essential to the successful physician.

A Society for the Conservation of Vision Organized in Philadelphia.—Acting under the auspices of the commission appointed by the society, laymen and doctors have formed the Pennsylvania Society for the Conservation of Vision. Aroused by learning that this country has 100,000 blind people, an active campaign is under way against ophthalmia neonatorum, needless eye injuries in the trades, trachoma, wood alcohol, wrong lighting of buildings, and like causes. In addition to a large number of distinguished laymen, acting as advisory members, the Commission on Conservation of Vision includes Dr. William Campbell Posey, Wills Eye Hospital, Philadelphia, chairman: Dr. William W. Blair, University of Pittsburgh; Dr. Clarence P. Franklin, of Philadelphia; Dr. C. M. Harris, of Johnstown; Dr. Edward B. Heckel, of Pittsburgh; Dr. T. B. Holloway, University of Pennsylvania, secretary; Dr. Wendell Hall, Reber, Temple University, Philadelphia; Dr. Edward Stieren, of Pittsburgh; Dr. Lewis H. Taylor, of Wilkes-Barre; Dr. William Zentmayer, Wills Eye Hospital, Philadelphia; Dr. Samuel G. Dixon, Commissioner of Health of the State of Pennsylvania, Harrisburg, honorary chairman.

Medical Faculty of the University and Bellevue Hospital Medical College.—The following new appointments and promotions in the medical faculty of this institution have been announced: Dr. William R. Trigg, professor of dermatology and pathology; Dr. Lewis K. Neff, clinical professor of medicine; Dr. William H. Luckett, clinical professor of surgery; Dr. George H. Kirby, assistant professor of medicine; Dr. Samuel A. Ewing, assistant professor of physiology; Dr. Charles Krumwiede, lecturer on bacteriology; Dr. Edward S. McSweeny, lecturer on the management of tuberculosis institutions; and Dr. Arthur G. Keane, clinical lecturer on surgery. Mr. John F. Nelson, instructor in surgery; Dr. Walter W. Griffin, instructor in surgery; Dr. George A. Keenig, instructor in surgery; Dr. John H. Carroll, instructor in medicine; Dr. John H. Wycoff, Jr., instructor in medicine; Dr. John A. Boll, instructor in medicine; Dr. Emanual D. Friedman, instructor in medicine; Dr. William H. Boese, instructor in medicine; Dr. Frederick W. Rice, instructor in obstetrics; Dr. William E. Bailey, instructor in clinical medicine; Dr. Robert McVicker, instructor in orthopedic surgery; Dr. Richard T. Atkins, instructor in orthopedic surgery; Dr. Alfred Kahn, instructor in otology; Dr. John J. Rothwell, instructor in dermatology; Dr. Clement J. Halperin, instructor in dermatology. Dr. Egebert Le Fevre is dean of the faculty and Dr. S. A. Brown is secretary.
Path of Progressive Literature.

**BERLINER KLINISCHE WOCHENSCHRIFT.**

Sources of Error in the Phenolsulphonephthalein Test for Kidney Function.—M. Roth finds that the reagent made by different chemical firms is not uniform and therefore gives altogether varying results. The excretion percentage with German preparations is eighteen to twenty per cent. less than with the American products. The application of the drug must be carefully made, and care should be taken that none of the substance is lost during injection. None of the urine must be lost when measuring the amounts excreted. The injection is made into the muscles of the lumbar region. Intralumbar injections have shown subnormal values. In women, disease of the genitals and pregnancy are contraindications for the test.

Intravenous Injection of Toxynon, a New Mercurial Preparation, in Syphilis and Nonsyphilis.—C. Gutman’s article in this and the previous number says that this new preparation, forty-eight per cent. of which is acetaminomercuric benzoic sodium, causes a rise in temperature after its first intravenous injection in syphilis and nonsyphilis which is much more pronounced in the former than in the latter. This leads to the conclusion that it possesses, besides a toxic effect, also a specific spiriloideal one. It is remarkable that the organism soon accustoms itself to the remedy; and the second injection is taken better than the first: most of the patients do not show a febrile reaction after later injections. Another striking fact is that all patients, with one exception, treated with toxynon did not have a febrile reaction after subsequent injections of salvarsan. This fact supports the supposition that toxynon has a specific action upon the spirochete and lessens or prevents the toxic action of salvarsan.

Dose and Methods of Application of Radioactive Substances in Internal Diseases and the Results Obtained.—Gudzent has shown by comparative experiments with varying doses of radium emanations that from three to five M. E. pro litre air inhalations in fifty-nine per cent. of the cases yielded therapeutic results, and that no more is accomplished with concentrations four to seven times as strong. The nervous anemic patients do not seem to bear the larger doses as well as the small ones. Of all diseases, gout and chronic articular rheumatism were most influenced by the radium treatment and the advantage of inhalation as against the drink cures was plainly marked in these diseases. Sciatrica, diabetic neuralgias, and Basedow’s disease are very much improved by this method of treatment. The results from thorium emanations and from these of thorium x were decidedly less favorable than those from radium.

Local Amyloidosis.—G. Herxheimer and A. Reinhart report a case of local amyloid formation in the mucous membrane of the urethra in a healthy man, twenty-seven years old. The amyloid particles were so massively imbedded in the otherwise intact and slightly reacting inflammatory mucous membrane that they gave the impression of a tumorlike formation. The cause remains unknown, since there is no history of a chronic inflammation or mechanical trauma.

Pathogenesis of Biliary Peritonitis without Perforation of the Gallducts.—M. Askanazy reports another case of biliary peritonitis without perforation of the gallducts. In this case, too, there was present a progressing injection of a complicated gallstone disease. The cause of the peritonitis lay in a so-called Luschka’s sinus duct which ran from the surface of the mucous membrane deep into the tunica fibrosa, i.e., into the subserosa, and contained incipient gallstone concretions. The inclination of necrotic tissue to absorb bile substances, and the exudation directed against the surface of the peritoneum, explain in a measure the possibility of the formation of a biliary peritonitis without perforation.

Serumtherapy in Toxososes of Pregnancy.—F. Wolff injected ten c. c. of the nonactivated serum of a healthy woman in the puerperium (fourteen days) into the gluteal region of a gravid woman suffering with severe urticaria; prompt healing resulted. This proves that a few weeks after delivery there is present in the circulating blood protective serums against placentalchorionic proteid.

Psychoses of Pregnancy.—C. A. Passow relates the case of a para V, with hereditary taint, who went through her first four pregnancies without any disturbance whatsoever, but suffered from a severe melancholia during her fifth pregnancy. A peculiar discoloration of the skin and a protrusion of the eyeballs pointed to a somatic disturbance (Basedow’s disease). The pregnancy was artificially interrupted because of progressive mental and bodily weakness. Recovery followed.

Tendon and Muscle Reflexes and the Signs of Their Diminution and Increase.—E. Trömmel states that all tendon, joint, bone, periosteal, and fascial reflexes are nothing more than true muscle reflexes. Every true muscle possesses the physiological property of reflex irritability. But normally there are great differences in the degree of irritability. With very few exceptions reflex contractions can be produced in the triceps, biceps, supinator longus, quadriceps, adductor, gastrocnemius, and the flexors of the knee. Absence of a number of these reflexes, the proper technic being applied, should excite the suspicion of an organic cause. The pathological superreflex is characterized by a series of phenomena: Increase in the sphere of irritability, contrari irritability of muscles, lively percussion muscle irritability, clonic reaction, and reflex crossings.

Kidney Function in Inflammation of the Kidney Due to Sublimate.—M. Ghirow observed the excretory relations of harmless coloring substances and poisonous substances (sublimate) in the kidney of rats by means of a specially constructed illuminating apparatus which permitted the observance of the function of the kidney epithelium together with the circulation and the way by which coloring matters leave the organism during their excretion. Anilin blue solution is rapidly excreted in large quantities from the glomeruli,
partly absorbed in the tubules, and slowly, step by step, excreted. A similar process is observed after sublimate injections; but in the second case because of the action of the poison there are structural and functional changes, dilatation of the blood capillaries, slowing of the blood stream, diminished transparency of the cell protoplasm, and a slower excretion of secondarily injected colored particles. By artificial increase of the blood pressure it is possible in the first stage of acute nephritis to hasten the excretion of the coloring matter.

A Simple Instrument for Determining the Number of Bacteria.—E. Rosenthal describes minutely a new instrument and a simple, reliable method for estimating the number of bacteria. This method will find application in the most diverse branches of bacteriological and clinical investigations.

Treatment of Disturbances of the Internal Secretion of the Ovaries by Glanduvin (Extractum Ovariæ).—J. Hirsch recommends the injection of this extract in climacteric disorders of the normal menopause, in climacterium praecox, and in dysmenorrhoea due to subfunction. It was found useless in one case of intermenstrual pain. It was used in sixteen cases of scanty menstruation and amenorrhoea; fifteen women were cured. One of two cases of the dermatoses of pregnancy was favorably influenced. In pruritus vulvae one of two cases in pregnant women showed a good result. In nineteen cases of hyperemesis of pregnancy, nine cases were favorably influenced.

CORRESPONDENZ-BLATT FÜR SCHWEIZER AERZTE.

Distilled Water in Medical Practice.—A. Barladean questions whether distilled water is the best means for the administration of salvarsan. He credits Wechselmann with being the first to call attention to the idea that certain toxic effects depended on the bacteria contained in the distilled water, rather than on the salvarsan, and brings together the observations of other writers together with his own on this subject. He found that ordinary distilled water contained many bacteria, and that although these were killed by boiling, their dead bodies caused trouble when the water was injected into the veins. Mueller, he says, examined sixteen specimens of distilled water obtained from different pharmacies, and found only two in which the germ content was less than 100,000 to the c. c. One contained 6,050,000 to the c. c., and two over 700,000. Distilled water is generally kept in bottles that cannot be thoroughly cleansed, and alkali from the glass and metals from the retort add to the impurities of the water. He insists that these impurities may even modify the effect of drugs taken by the mouth, and maintains that the chemical test of distilled water should be supplemented by biological and bacteriological tests, as well as by that of its electric conductivity.

Pulmonary Tuberculosis in Great Altitudes.—H. Philippü writes on the treatment, F. Egger on the indications for and against great altitudes in pulmonary tuberculosis. According to the latter it would seem to be only early or incipient cases that are fitted for mountain air, while his contra-indications include advanced cases and those with serious complications.

PARIS MÉDICAL.

Antitetanic Serum in Wounds of the Eye.—Vinsonneau reports a case of slight abrasion of the conjunctiva in which enucleation became necessary because of panophthalmitis, and cephalic tetanus appeared two days after, soon proving fatal. No foreign body could be found in the eyeball or orbit. Antitetanic serum should be always given in wounds of the eye in which the vulnerating body has been in contact with the soil, and should be used as frequently as possible even where this has not been the case. Where tetanus actually develops, injections of serum should be made in the sphenoidal fissure and optic foramen. This will be facilitated by the previous laying open of the wound, if it involves the orbit, or by enucleation, if the eyeball has been injured.

Mushroom Poisoning.—R. Le Roy states that in one month of the year 1912 there occurred in France, to his knowledge, 271 cases of mushroom poisoning, with ninety-six deaths. The number of cases of this kind has been rapidly increasing in recent years. Le Roy insists that there is no empirical means of distinguishing good mushrooms from the harmful ones; accurate knowledge of the botanical characteristics of each variety is alone to be depended upon. He shows the fallacy of a large number of popular rule of thumb methods of mushroom selection, and points out the inefficiency of various supposedly detoxicating procedures, such as drying the mushrooms, removing their pigmented top layer, boiling them with salt or vinegar, macerating in cold water for twenty-four hours, and the ingestion of vegetable or animal charcoal.

PRESSE MÉDICA莱.

Pulmonary Sporotrichosis Simulating Tuberculosis.—C. Laurent reports having seen eight cases of sporotrichosis in a year and a half. Most of these were of the commoner varieties, presenting cold abscesses, ulcer on the forearm, tibial osteitis, etc. In one case, however, there were combined with a subcutaneous abscess and discharging lesions of the right ulna, right first metatarsal and left cuneiform bones, typical signs of tuberculosis in both apices. Cultures from the sinuses yielded the specific Sporotrichum Bertramianii, but the sputum, which was scanty, showed neither this organism nor the tubercle bacillus. The temperature was practically normal. A complete cure was effected in a month by the administration of four grammes of potassium iodide daily.

SEMÉAINE MÉDICA莱.

Renal Factor in Glycosuria.—R. Lépine, having observed that in phosphoridin glycosuria the blood of the renal vein contained more free sugar and less combined sugar than that of the renal artery, embodies this fact in a new theory of the cause of
this form of glycosuria. He looks upon phloridzin glycosuria as being due, not as Pavy and others have supposed, to a new formation of sugar in the renal cells, but to excessive transudation through the walls of the renal capillaries of sugar liberated from the combined form through the effect of the phloridzin. The phloridzin also acts, according to his theory, by creating in its elimination pores or interstices in the renal vascular endothelium through which the glucose set free can readily pass, i.e., it increases renal permeability to the glucose. Lépine would substitute for "renal" diabetes the term "diabetes without hyperglycemia" as being more definite and exclusive. Such a condition is met with clinically, especially in women in the later months of pregnancy, glycosuria appearing after the ingestion of sugars or starches in amounts which would not produce it in the normal individual and in spite of the fact that examination of the blood shows no hyperglycemia. In view of the fact that certain organs are overactive during pregnancy, this form of "renal" glycosuria may perhaps be analogous to that which follows the injection of organ extracts. As for the cases of diabetes without hyperglycemia recently reported by a number of authors, they are far from constituting a homogeneous or uniform group.

**REVUE MÉDICALE DE LA SUISSE ROMANDE.**

*August, 1913.*

**Emotional Reactions as a Factor in the Production of Psychopathic Disorders.—** Dubois points out that, if emotional reactions, e.g., fear, be accepted as the basis of human conduct, it should not be overlooked that such emotional reactions are always preceded by a rapidly executed mental estimation of the value or significance of the influences to which the individual is subjected at the time. In many instances this estimation is faulty, and it should be one of the aims in psychotherapy to correct the wrong conceptions of environmental events upon which the patient's fears depend.

**Hemorrhagic Myeloid Leucemia.—** II. Ter-Barsegian, concluding an article begun in the preceding number, states that myeloid leucemia is frequently accompanied by cutaneous, mucous, or visceral hemorrhages. In certain cases these hemorrhages are so abundant or numerous that an actual hemorrhagic form of myeloid leucemia can be spoken of; the author reports six cases of this kind. The hemorrhagic manifestations may either continue in a chronic manner from the beginning of the disease or appear in pronounced form only in the terminal stage of the disease. Among the causes of the hemorrhages are a change in the condition of the blood, exaggerated diapedesis, alterations in the vascular walls, slowing of the blood stream, etc. The prognosis in this form of leucemia is even less favorable than in the cases not complicated with hemorrhage. In the treatment, which coincides with that of leucemia in general, special caution should be exercised to avoid surgical traumatism and even subcutaneous injections.

**Moriz Weiss Reaction for Urochromogen.—** E. Cottin reports the results obtained with this reaction in nearly 300 cases, about one half of which were tuberculous. In most instances parallel tests with Ehrlich's diazo reaction were made. The Moriz Weiss reaction possesses the same clinical significance as the diazo test, but has advantages over it in being simpler, giving an immediate result, and being of a greater degree of sensitiveness. It is carried out by filling a tube one third full of fresh urine, adding twice this amount of water, pouring one half of the resulting mixture in another tube as control, adding to one tube three drops of a freshly prepared one in 1000 solution of potassium permanganate in distilled water, and mixing. In a negative reaction the color of the urine remains the same or is rendered slightly brownish, while if urochromogen is present the preexisting color of the urine is accentuated to a golden yellow. Where there is doubt as to the result, the test should be repeated, using less water or more of the permanganate solution added; to dark urines—with urobilin, bilirubin, etc.—finely powdered ammonium sulphate should first be added to the urine, which is then to be filtered fifteen minutes later. From the series of cases studied Cottin concludes that a persistently positive Weiss reaction in the urine of tuberculous patients is of unfavorable prognostic significance, even in patients whose general clinical condition appears to warrant the hope of improvement. The reaction proved positive in the terminal stages of various other affections—pneumonia, erysipelas, nephritis, heart disease with pulmonary embolism, empyema, hemiplegia, and grave essential anemia. In all these cases there could already have been no doubt of an early fatal ending.

**Warmed Ether in Anesthesia.—** C. Julliard reports laboratory experiments and comparative observations in 203 clinical anesthesias, conducted in order to prove or disprove the advisability of using ether previously heated to boiling in anesthesia. The author is led absolutely to deny that by heating ether either the temperature or tension of the anesthetic vapor in the mask can be altered, except for a very short time. Ether heated to 33° C. seems at first more pleasant to the patient than ether at air temperature, say 23° C.; this appears to be due to the early increase of vapor tension due to the heating. As soon as the ether at 33° C. volatilizes, however, it becomes cooler, the temperature of the vapor drops, and very soon conditions are exactly the same as though the ether had not been heated at all. Heating the ether has no effect on the rapidity of onset of anesthesia or the amount of ether required, for heated ether volatilizes quickly, cools rapidly (reaching the freezing point in four minutes), and therefore promptly loses the initial increment of vapor tension. Use of the inhaler devised by G. Julliard is advised, as the temperature of the mixture of ether vapor and expired air in it is from 23° to 24° C., which is about 20° higher than with Sudeck's inhaler. The temperature is practically the same whether the ether has previously been or not been heated. Inhalers of large capacity are to be preferred to small ones, as the more remote the seat of the volatilization of ether in the inhaler is from the patient's mouth, the higher the temperature of the mixture of gases in the inhaler. Pneumonia and other complications following ether anesthesia are not due, however, to low temperature of ether vapor.
The Action of Strophanthin upon Cardiac Tissue.—A. J. Clark finds that, in perfusion experiments with the isolated heart of the frog, strophanthin is opposed in its systolic effect by the presence of acid, a hypodynamic condition of the muscle, and by an absence of calcium. In improving the force of the heart’s contraction, as well as in causing systolic standstill, the action of strophanthin is very closely similar to that of certain alkalies. On the other hand, in its influence on the rate of conduction it shows no resemblance to the effects of alkalies. This action seems to be of an entirely different nature from its systolic action. It is interesting to find that the increase in the force of the ventricular contraction under the influence of the drug is much greater in the case of hypodynamic hearts than in that of normal ones. This suggests a possible parallel in the cases of the normal and diseased human hearts.

Maximal and Minimal Blood Pressures.—J. F. Halls Dally calls attention to the fact that the blood pressure for any individual is not a constant quantity, but is ever fluctuating, due to changes in the tonus of the vessel walls, variations in the peripheral resistance, alterations in the volume of the blood, and the rate of the heart beat. The maximal and minimal pressures between which the arterial pressure normally varies are the valuable criteria to be determined in every case. It is also fallacious to speak of “the systolic” blood pressure; we should speak of the brachial, the femoral, or other definite systolic pressure. It has been assumed, heretofore, that arterial elasticity is a fixed quantity for each artery, and that it does not vary during health. Nothing is farther from the truth, if the suggestion be confirmed that the arteries are capable of altering their rigidity or resilience under the influence of the vasomotor nervous mechanism, or from other causes. The blood pressures—systolic and diastolic—are of decided prognostic value, for instance, if, in a case of high pressures, both continue to rise in spite of treatment the outlook will be unfavorable. A caution is given in the reading of the two pressures; that they be taken at the same time and by the same method of recording. The author finds the Pachon oscillometer a very satisfactory instrument for this purpose.

On the Genesis of Cancer.—Arthur Turnbull holds the only definite fact in the etiology of cancer so far established to be that irritation or chronic mechanical strain leads to cancer. He has undertaken to study the matter of the influence of strain upon tissues, for which purpose he has taken measurements upon the femora of some 700 human beings. From 25,000 measurements he believes that he has established “a principle of first magnitude in the cancer problem—namely: There exists a re-
lation between the strain to which a tissue is exposed and the extent to which that tissue varies." The principle offers a rational explanation of the transformation of normal into cancerous tissue without having to seek any external factor, such as parasites.

Electragol in Smallpox.—R. Denman accidentally observed the abortion of a case of smallpox occurring simultaneously with plague, for the latter of which diseases electragol was administered. Thinking that this drug might be accountable for the curative effect, he has tried it in a fair number of cases of confluent smallpox, or such as were even worse. His results have been very excellent, reducing the mortality from fifty to twenty per cent. He gives from ten to twenty cubic centimetres intravenously daily for three or four consecutive days. For the best results in ordinary confluent cases, and to be of any value at all in the severe hemorrhagic or septicemic cases, it must be given at the earliest possible moment.

A Note on Cardiospasm.—Alfred C. Jordan has observed the great constancy, in cases of cardiospasm, of the distended, "writhing" duodenum and of delay in the lower ileum and large intestine, both typical of chronic intestinal stasis. It is possible that in a certain number of cases of this condition the etiology of the spasm may lie in the intestinal stasis, it being a reflex, or toxic manifestation.

Secondary Rays in Connection with Ionization. — An interesting suggestion is made by John D. Harris, to the effect that the introduction of certain metallic ions into the deeper tissues by ionization may increase the action of x rays through the liberation of secondary x rays from the deposited metal. He has obtained good results from the use of the zinc ions in several cases of tuberculous or malignant ulceration. The use of potassium iodide in connection with x rays cured a moribund patient with actinomycosis who had resisted all other forms of treatment.

LANCEIT.
October 11, 1912.

Hard versus Soft Water.—Supplementing his previous report of 1910, John C. Thresh has compared the death rates of several communities for the period of five years from 1907 to 1911 with reference to the possible effects of the water supply. He also gives similar statistics for the year of 1912. The waters supplying the several communities varied from very soft and slightly alkaline to very hard, that is to 20° to 30° of hardness. Both urban and rural districts are included in the statistics. The comparison shows that there is no appreciable difference in mortality rate between these differently supplied communities—the hard water areas give a rate from 0.1 to 0.2 per mill higher than corresponding soft water regions. He shows, further, that filtered water from rivers polluted with sewage has no effect upon the death rate. The incidence of death from cancer, phthisis, and typhoid fever was also investigated with reference to the water supply, and it was found that the degree of hardness was without effect here as with the general mortality.

Arteriovenous Anastomosis for Impending Gangrene.—Charles Goodman calls attention to the varied results reported by different surgeons after performing this operation, and believes it is due to the difference in technic, and the lack of any uniform method of procedure. The author has performed fifteen of these operations on patients varying in age from twenty-eight to eighty-seven years. He had one death and seven other failures. One of these cases was due to the use of a side to side anastomosis, and three of the other patients should not have been operated upon. He has had six complete successes, all done by direct end to end union after the method of Carrel. Special caution must be exercised in the union not to injure the intima of either vessel in order to avoid clotting. In all the cases the cold foot became warm and pink, pain was relieved, filling and pulsation of the superficial veins was prompt, and there was a return to normal of the parts threatened with gangrene.

Formation of an Artificial Vagina.—Victor Bonney details a case in which it was necessary to perform this operation to restore the health of a girl of nineteen, who had become suicidal as the result of her knowing of the total absence of a vagina. Bonney used Baldwin's method of transplanting a section of the ileum into the pelvis, leaving its mesenteric vascular attachment intact. The result was excellent. The method commends itself especially because it is the only one by which subsequent cicatrical contraction of the artificial vagina is avoided. There have been only eleven other similar cases reported in the literature, and the opportunity for the operation is very rare. Nevertheless, Bonney discusses the ethical aspects of the procedure. He believes that it is justifiable only in women after the appearance of puberty, because so many of the cases of absence of the vagina are associated with congenital absence of the ovaries also. If the woman has shown signs of normal sexual feelings and for other reasons the operation seems called for it is then justifiable, even though the woman can never bear children. It must be borne in mind that the operation is associated with considerable danger, and is therefore not to be undertaken except where the demand is pressing.

PRACTITIONER.
September, 1912.

The Treatment of Anemia.—W. H. Wilcox gives the following measures: The immediate treatment of acute anemia, due to severe hemorrhage, is directed, after the bleeding is checked, toward preventing death from collapse and shock. The foot of the bed should be raised, hot water bottles applied, the limbs and abdomen covered with warm cotton and bandaged. Absolute rest and quiet are essential. Warm saline solution should be given subcutaneously and by the rectum, or, in extreme cases, infused into a vein, two pints being used. Oxygen, or better oxygen bubbled through absolute alcohol, should be given, and in extreme collapse and shock, hypodermic injections of pituitary extract of strychnine. These last should not be given when the bleeding is due to phthisis or
gastric ulcer and continuing, but morphine should be injected instead and repeated if necessary. In chlorosis the rest in bed should be for at least four weeks, and longer if the hemoglobin is still much below normal, and particularly if the heart is dilated with hectic bruits and a rapid pulse. Afterward the patient should have as much fresh air as possible without physical overexertion. The diet should be as liberal as the gastric condition of the patient will permit. Her taste may be complied with, provided that an ample allowance of foods rich in protein is taken. Iron is most important and should be given in a mixture determined by the condition of the stomach. Several prescriptions are given as examples, of which we will copy one for each condition. When there is no gastric irritation:

R  Ferri sulphatis, gr. iii;
Magnesii sulphatis, 5j;
Acidi sulphurici dilut, m.v;
Syripi aurantii, 3j;
Acque chloroformi, q. s. ad. 3j;
M. S.: To be taken three times a day after meals.

When there is slight irritability of the stomach:

R  Ferri sulphatis exsiccati, gr. ij;
Extracti aloe siccatis, 3j;
Extracti cascarae sagrae, gr. j;
Pt. one pill. Take three times a day after meals.

When irritability of stomach is marked:

R  Ferri et ammonii citratis, gr. viij;
Sodii bicarbonatis, gr. x;
Syripi aromatichi, 3j;
Acque chloroformi, q. s. ad. 3j;
M. S.: To be taken three times a day after meals.

About twenty-four grains of powdered hemoglobin should also be taken t. i. d. In some cases the addition of small doses of arsenic is valuable. When the gastric irritation is very marked it may be necessary to give for a few days a mixture of bismuth and alkali, with a liquid diet. When the amount of hemoglobin has returned to normal treatment with Bland’s pill, or some other good preparation of iron, must be continued for some months. In pernicious anemia complete rest in bed is essential until all signs of cardiac dilatation have disappeared and until the pulse rate is below eighty. In carrying out other measures it must be remembered that the cause is often some intestinal toxemia, or possibly oral sepsis, and that in most cases the gastric secretion of hydrochloric acid and ferments is almost nil. For the details the reader is referred to the original article. In splenic anemia and leucocytopenia the general lines of treatment are the same as for pernicious anemia. In addition the application of the x-rays over the spleen, every ten days at first and at longer intervals afterward is often of service. The treatment of cases of secondary anemia resolves itself into the treatment of the condition causing the anemia, with the addition of the measures described under chlorosis.

Some Pelvic Disorders in Relation to Neurasthenia.—Carlton Oldfield says that pelvic disorders have no specific action in causing neurasthenia. Pelvic complaints, with the exception of disorders of menstruation, are as often as not unassociated with physical signs, and due to a general neurasthenia. Certain conditions, such as a slight exposure of the vaginal wall, cervical erosion, laceration, retroflexion of the uterus, prolapsed ovary, ovaritis, and cystic ovary, do not produce symp-toms, and do not require treatment. Chronic pelvic inflammation, calling for operative treatment, sometimes exists apart from recognizable tumor formation. Greater care is necessary, before, during, and especially after operation, to prevent post-operative neurasthenia. Before operating upon neurasthenics with gross disease, and before operating in cases without demonstrable physical signs the surgeon should seek the advice of the physician.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

October 18, 1913.

Radiographic Studies of the Gastrointestinal Tract in Infants, by H. D. Chapin.—See this Journal for July 5th, p. 40.

A Study of the End Results of the Baldy-Webster Operation, by J. O. Polak.—See this Journal for June 28th, p. 1367.

Radium in Internal Medicine, by L. G. Rowntree and W. A. Baetjer.—See this Journal for July 5th, p. 59.

Rupture of a Mediastinal Lymph Node into the Bronchus, by A. L. Goodman.—See this Journal for July 5th, p. 40.

Roseola Infantum, by J. Jahorsky.—See this Journal for July 5th, p. 41.

Disarticulation of the Knee Joint.—F. J. Gaenslen says that in conditions requiring amputation through or near the knee joint the surgeon is influenced in his choice of an operative method in the first place by the pathological condition present which determines how much of the limb must be sacrificed, and secondly by the desire to leave the patient as useful a stump as possible. Referring incidentally to the Carden and Gritti methods, the author describes a method of procedure which he devised for the purpose of securing a broad weight bearing surface utilizing the patella in addition to the condyles, in contrast to other methods. The principal points in the technic are the preservation of the patella and the extensor apparatus by division of the patellar liga-ment close to the tibial tubercle; lengthening of the quadriceps tendon to allow the patella to be brought down into apposition with the lower surface of the femur; and the performing of an arthrodasis between the patella and femur in the intercondylar space at such a point that the pressure bearing surface of the patella will lie on a level with the condyles.

Joint Disease Due to Infection from Other Parts of the Body.—J. W. Cokenower finds that the frequency of joint disease and its often uncertain etiology constitute a problem which has largely contributed to the unsatisfactory differential diagnosis of the various kinds of joint ailments. On account of the paucity of references to this subject in the literature of the last four years, he wrote a number of orthopedic and general surgeons for clinical reports, and as the result of this investigation he concludes that the differential diagnosis of arthritis frequently depends, not on the examination of the local condition, but on the presence or absence of preceding or associated le-
tions in other parts of the body. Another condition of the joints which he says must not be overlooked in the diagnosis, because it is often taken for inflammation when in fact it is not, is edema due to effusion.

The Injection Treatment of Tuberculous Joints.—L. W. Ely states that the employment of this practice goes back for over thirty years. In 1881, von Mikulicz used iodidioform, and since then many other substances have been employed, among them bone charcoal, iodine, phenol, arsenic trioxide and corrosive sublimate, aciddulated solution of calcium sulphate, zinc chloride, balsam of Peru, naphthol camphor, and formaldehyde solution. Iodidioform has been advocated most strongly and persistently, but if we examine carefully the evidence for this agent after thirty-two years of trial we find that it consists almost exclusively of unsupported clinical opinion. This does not necessarily condemn it, but when an approximately equal weight of unfavorable clinical opinion is produced on the other side, we are justified in demanding some tangible proof of its usefulness. Failing this, we should adopt a form of treatment the efficacy of which rests on something else than contradictory clinical experience. Having stated that the other substances mentioned rest their claims on much the same basis as iodidioform, the author expresses the opinion that it is as rational to attempt to cure a tuberculous joint by injection of the synovial cavity as to cure a tuberculous lung by injection of the pleural cavity.

MEDICAL RECORD
October 18, 1913.

The Cure through Genitourinary Surgery of Arthritis Deformans and Allied Varieties of Chronic Rheumatism.—Eugene Fuller states that his experience with and knowledge of these affections came as a sequel to preceding work in connection with gonorrheal rheumatism, so called, and that in previous communications he had expressed the positive opinion that in its more chronic forms a toxemia independent of the gonococcus systematically absorbed from infected seminal vesicles was responsible for the trouble. In former articles he had shown that various groups of subjective symptoms had been found to be curable as a result of the removal of lesions connected with the seminal vesicles through a resort to seminal vesiculotomy. The present paper dealt with one group of cases representative of a very chronic and advanced form of rheumatism which he had found to be likewise curable. In certain of these old chronic cases a marked seminal vesiculitis and characteristic rheumatism would be found, although all questions as to the previous existence of a gonorrhoea would receive negative answers. In such cases it was observed that the rheumatism would disappear with the postoperative disappearance of the seminal vesiculitis, just as in the cases in which there was a preceding history of gonorrhoea. In a series of sixty-nine cases in which the operation was undertaken for the relief of rheumatism there was one death, the patient being an alcoholic with granular kidneys. Between twenty and twenty-five represented extremely chronic or most advanced conditions of rheumatism, and in a number of these sufficient time has not yet elapsed for the end result to be attained. The more acute cases, aside from the one in which death occurred (and that patient stated a week after his operation that all his rheumatic symptoms had disappeared) were all discharged from hospital in a very satisfactory condi tion. After remarks on the character of some of the lesions observed in his cases and on certain features of the operative procedure, the author presents nine case reports.

The Scope of Radiographic Methods, from a Clinical Viewpoint, with Some Illustrative Cases.—I. A. Wing holds that the x-ray is almost indispensable in the following types of cases: Fractures, types of arthritis, diseases of bone in general, foreign bodies in the tissues, calculi in the kidney, ureter, and bladder, aneurism and dilatation of the arch of the aorta, lesions of the esophagus, conditions involving the colon, and gastric cases. His conclusions are: The x-ray should not be regarded as something apart from other methods of examination, but as a supplemental method, and often a very valuable one. It should be employed more frequently, and clinicians in general should be more familiar with its scope of useful ness, as well as its limitations. It is very desirable that the radiographer and the clinician be in close relation in the matter of radiographic interpretation, so that the entire evidence in a given case can be weighed in a consistent manner.

Syringomyelia; with Pathological Findings.—E. P. Bernstein and S. Horwitt first present some remarks on the present status of syringomyelia, or cavitation of the spinal cord, stating that the cavity may be so small as to give rise to but few symptoms, but by extension may compress or destroy the posterior columns, posterior gray horns, and even the crossed pyramidal tracts. Then, again, it may be of various shapes, with irregular extension in various directions, thus giving rise to most irregular symptom complexes. Clinically the disease may present an immense variety of symptoms, and these, for convenience, are arranged in a number of groups. With regard to the association of the cavities with gliosis, some are inclined to consider the latter a secondary process, but the view accepted by most observers of to-day is that the gliosis is primary and the cavitation a result of degeneration occurring in the glia neoplasm. The authors give an elaborate analysis of the pathological findings in the case of a female patient who died in less than a month after admission to hospital. For nine years she had suffered from attacks of pain over the sacrum and in the left lower extremity, which gradually became more frequent and involved the right leg also. On admission both extremities were helpless (flaccid paralysis), with anesthesia, areas of dissociated sensation, and extensive bedsores with deep ulcers over both buttocks.

AMERICAN JOURNAL OF TROPICAL DISEASES AND PREVENTIVE MEDICINE.
August, 1913.

Experiences with Beri Beri.—V. G. Heiser reports that the beri beri which formerly prevailed at the Cullon leper colony in the Philippine Islands was arrested by the use of unpolished rice, that is, a rice containing at least 0.4 per cent. of pho-phorus.
pentoxide, and reappeared when unpolished rice was for a time unavailable, the use of polished rice, that is, a rice containing only 0.2 per cent. of phosphorus pentoxide, being resumed. The quantity of phosphorus is believed to be of importance only as an index as to the amount of the outer layer or pericarp of the rice grain that has been removed, the identity of the substance in the polishings, lack of which causes beri beri, but having as yet been determined.

Polyneuritis Gallinarum Caused by Different Foodstuffs.—Creighton Wellman and C. C. Bass describe experiments which led them to conclude that glucose and tale, used commercially to impart to milled rice a polished appearance, play no part in the production of polyneuritis gallinarum, a disease of birds and fowls which is believed identical with beri beri in man, and which results from an exclusive diet of "polished" rice. Legislation or regulations against the sale of "polished" rice, based upon the fact that polyneuritis gallinarum results from feeding it as an exclusive diet, are not warranted. It was found that corn grits, boiled beet potatoes, boiled Irish potatoes, sago, macaroni, puffed rice, cream of wheat, and ordinary wheat flour, fed to chickens or pigeons as an exclusive diet, produced the disease as certainly, and in a few instances even more rapidly, than did rice.

Peripheral Neuritis in the Amazon Valley.—Carl Lovelace states that among 563 cases of peripheral neuritis clinically and anatomically indistinguishable from beri beri, treated in a railway hospital in North Brazil, there were many in which the factors of defective diet and of a rice diet could be positively excluded. Since it has nevertheless been conclusively shown by Fraser and Stanton and others that the beri beri symptom complex may be induced by a diet of polished rice, and considering the number and diverse characters of the agents known to cause multiple neuritis—lead, arsenic, alcohol, diphtheria, typhoid fever, syphilis, etc.—it is highly probable that the term "beri beri" has been used to cover not a single disease, but a group of diseases, more or less indistinguishable clinically.

Sprue in Porto Rico.—B. K. Ashford calls attention to a condition apparently genuine sprue, as a very common and fatal disease in Porto Rico. At least four cardinal signs are essential to a positive diagnosis: 1. The typical sprue tongue, sometimes glazed and shiny, but at other times, during an exacerbation of the stomatitis, red at the tip and edges, with little vesicles surrounded by a red areola, or completely raw; 2. the small liver; 3. the pasty or frothy stools, large, evil smelling, and light in color; 4. constant and distressing gas production in the intestine. Of the eighty-six cases met with by the author, most were in the well to do class. The mouth symptoms showed a marked tendency to alternate with those of the bowel. Hypochlorhydria was constant, carbohydrate digestion very defective, and absorption of fats greatly reduced. The terminal stage of sprue is one of marasmus toxemia," with intense anemia. The disease cannot be successfully treated unless starches, sugars, and fats are wellnigh eliminated from the diet. The author reports eight cases treated with a diet exclusively of milk, taken warm through a straw every hour and a half, together with a full dose of castor oil twice a week at bedtime, and on three successive days in each week one gramme of yellowed santonin, divided into three doses daily, and given mixed with olive oil. In some instances, the dose of santonin was reduced to 0.325 gramme a day. While marked improvement or recovery followed in each of these patients, eight other patients placed upon a milk diet alone, without drugs, all made a good recovery, and remained well from one to three years after.

Otosclerosis.—A. Denker states that investigations have shown that pathologic-anatomical foundation of otosclerosis has revealed the loss of movement of the stapes as the result of bony ankylosis in its framework or in the niche of the oval window and a progressive spongification of the bony capsule of the labyrinth, to which must be added, as shown by the histological examination in a large number of cases, an atrophic degenerative process in the nerve endings in the membranous labyrinth. The majority of investigators concur in the opinion that the condition is a primary bone disease of the labyrinth capsule and not an extension of inflammation from the middle ear. Various reasons have been advanced for the occurrence of the changes demonstrated. Heredity seems to be the most important etiological factor, although there is a possibility that the predisposition and not the disease is inherited. The coincidence of pregnancy with the beginning of the otosclerosis suggests a causal relationship between the function of the hypophysis cerebri and the ear disease. Alexander believes the cause may be of congenital origin. The variability of the lesions produced and the resulting symptom complex cause the disease to be divided into: 1, those cases in which the changes are located exclusively at the vestibular window and its vicinity, and have led to a bony fixation of the footplate; 2, those cases in which the appearance of multiple spongifying foci in the labyrinth capsule, with atrophic degeneration of the membranous labyrinth without stapes ankylosis; and, 3, those cases with bony fixation of the stapes plate, combined with other foci in the labyrinth capsule and with atrophy of the membranous labyrinth. The treatment so far has been unsatisfactory, but from the author's experience good results may sometimes be obtained by the internal administration of phosphorus.

June, 1913.

Removal of Adenoids by Direct Inspection.—Joseph C. Beck advocates the insertion of a small rubber catheter through the nostrils, bringing the ends out through the mouth, for the control of hemorrhage after the removal of the frenal tonsils and for direct inspection by traction on the ends of the catheter by an assistant at the time of the removal of the adenoid. This method seems especially efficacious when the adenoid vegetation is situated around the orifice of the Eustachian tube, and in the application of artery forceps to the posterior wall of the nasopharynx in cases of excessive hemorrhage after the removal of the adenoid.

Atrophic Rhinitis with Ozema.—F. P. Emerson believes that ozema is the sequel of a focal infection. The presence of a septal deviation causes a con-
pensatory hypertrophy of the middle turbinate, which is followed by a chronic catarrhal ethmoiditis interfering with drainage to such an extent that a subsequent active infection results in a sinusitis. The fetor and crusting are probably due to the direct action of a specific pus producing organism on the tissues, without any preceding true atrophic process.

Mastoid Operation.—W. Sohier Bryant advises that the mastoid operation when a mastoid abscess is present; when the mastoiditis is due to Streptococcus mucosus, in the presence of intracranial or hemic complications of middle ear infection; when the bone is of the solid variety, whether in acute or chronic mastoiditis.

ANNALS OF SURGERY.

Laryngectomy for Cancer.—G. W. Crile says that surgical experience has demonstrated that intrinsic cancer cannot invade hyaline cartilage; that it tardily, if at all, metastasizes; that it frequently follows in the wake of benign tumors and of syphilitic ulceration; that the immediate mortality is now well controlled; that the disability and deformity of the laryngectomized patient should have no weight in deciding for or against the operation; that special training and experience are required to thoroughly master the technic, and that if recognized early, and removed completely, intrinsic laryngeal cancer is perhaps the most curable cancer of the body. In view of the results obtained, there is no longer any justification for the pessimism which still disheartens the victim of laryngeal cancer and prevents him from utilizing his one chance of life.

The Preliminary Ligation of the Thyroid Arteries and of the Inferior in Preference to the Superior Artery.—William S. Halstead says that for the past two years or more he has tied the inferior in preference to the superior arteries and for the following reasons: The cosmetic effect is better; the wounds made for ligation of the inferior arteries are partly outside of the field of the lobectomy operations; as the inferior thyroid artery is usually larger than the superior, the effect of the ligation may be greater, and that the location of the inferior artery is less variable than that of the superior vessel, which is subject to great changes because of the inconstant position of the superior pole. He ligates the inferior thyroid artery as follows: A transverse incision from four to four and five tenths centimetres in length is made over the tendon of the omohyoid muscle precisely in the line of the Kocher collar incision as contemplated for the subsequent lobectomy. The fibres of the sternomastoid muscle are separated in line of the common carotid artery at the level of the omohyoid tendon. The thyroid lobe is exposed behind the posterior fibres of the sternothyroid muscle and drawn inward by a retractor designed for this purpose. The common carotid is retracted outward by a similar though by a somewhat shorter instrument, and the layers of the fascia covering the inferior thyroid artery are divided at the level of the omohyoid tendon. Dissection is then carried out solely with two long, delicate, blunt dissectors, for the artery is sometimes at a great depth (greatest when Graves's disease has been engrafted on a colloid goitre), and the space is only large enough, as a rule, to admit one finger between the deeply concave retractors. A special aneurism needle is used for carrying the fine silk ligatures around the artery. The wound is, of course, not drained.

Acute Perforating Sigmoiditis in Children.—J. Ransohoff reports two cases of left-sided lower quadrant intraabdominal suppuration and draws the following conclusions: 1. Although few cases of sigmoid diverticulitis have been found in children, no cases of diverticulitis have been recorded in children. 2. To designate in a general way, as is the present tendency, all left-sided lower quadrant suppurations as of diverticular origin is not warranted by the facts. Unless a diverticulum is shown, the diagnosis must be problematical. This applies, of course, very much more to children than to adults in whom all the recorded cases have occurred. 3. Leftsided appendicitis cases have been described with and without visceral transposition. 4. It has not been the writer's object to underrate the importance of the sigmoid diverticulum as the cause of the leftsided abdominal suppurations, but to call attention to other conditions, notably of the mucosa producing them, and particularly in children.

MONTHLY CYCLOPEDIA AND MEDICAL BULLETIN.

Adalin.—Paul Bartholow finds adalin a powerful nervous sedative. It is strongly hypnotic in doses of from fifteen to twenty grains. Such doses may accumulate; this is prevented by a daily saline purge. Large doses may also cause some heaviness of the head on the third day, which can be avoided by giving an effervescing draught containing a small dose of acetphenetidin. Doses of five grains three times a day suffice for sedative purposes in nervousness and do not produce habituation. The quantity of urine is slightly increased, probably owing to the urea contained in the drug.

SURGERY, GYNECOLOGY, AND OBSTETRICS.

Prostatectomy.—John B. Deaver says that where the prostate is without doubt malignant, tuberculous, or the seat of an incurable gonorrhea, and in cases of benign scirrhus enlargement successful prostatectomy can only be performed by the perineal route. He follows the technic of conservative prostatectomy devised by Young, not with the idea of saving the ejaculatory ducts, but because, by the fine exposure afforded by this method, it is possible to remove the greater portion of the diseased gland under guidance of the eye, and therefore with less danger to the contiguous structures. With the exceptions cited above, the suprapubic route is preferable because: 1. The approach to the prostate is simple and practically bloodless. 2. The excision of adenomatous growths is accomplished with ease. 3. The working field is large and under perfect control. 4. The prostate is accessible and can be made more so by digital pressure on its rectal surface and without the danger of injury to the bladder liable with the use of the tractors necessary in the perineal operations. 5. The muscular control
of the bladder neck is not disturbed since the internal vesical sphincter lies outside the line of cleavage, and incontinence is therefore less liable following this technic. 6. Permanent fistulae are less frequent after the suprapubic operation. 7. Sepsis occurs less than half as often as with the perineal operation. 8. Drainage is more nearly perfect. 9. Stones can be more easily removed. 10. Uremia is a less frequent sequel. 11. The mortality, in properly selected cases, is no greater and the percentage of permanent cures much larger. 12. Immediate postoperative complications, especially hemorrhage, are less often noted. 13. Sexual potency is maintained as frequently after the suprapubic operation as after the perineal, and the question of sterility is rarely of any consequence.

Regeneration of Bone from Periosteum.—S. L. Haas from a series of animal experiments concludes that: 1. Periosteum, especially in the presence of blood clot, has the power to regenerate bone. 2. Regeneration of bone is not solely dependent upon the presence of preexisting bone. 3. Regeneration of bone was never found excepting when periosteum was present.

An X Ray Study of the Mechanism of the Stomach after Gastroenterostomy.—J. H. Outland, E. H. Skinner, and L. Clendening draw the following conclusions: 1. Gastroenterostomy, if properly done, is a drainage operation. 2. After gastroenterostomy, if the stoma is at the lowest part of the stomach in the erect position, the food leaves the stomach almost exclusively by the gastroenterostomy opening. 3. Under these conditions the stomach is emptied with great rapidity. 4. Gastroenterostomy should be done only in the presence of pyloric stenosis, or pyloric spasm due to duodenal or gastric ulcer. 5. The gastroenterostomy opening should be made large and placed as close as is permissible to the pyloric antrum. In cases where the gastroenterostomy opening does not quite drain the stomach, the food leaves by means of the stoma and the pylorus. Even in these cases, however, the stomach empties itself faster than normal. 7. The clinical failures after gastroenterostomy are probably due to the cases of faulty implantation of the stoma.

Intussusception of the Stomach and Duodenum.—Henry Wade reports a case and states that benign tumors of the stomach are of occasional occurrence. The majority of these ultimately come to project within the gastric chamber and become pedunculated, forming gastric polypi. These polypi when situated adjacent to the pyloric antrum, ultimately produce occlusion of the pylorus by a ball valve action. This is indicated by the signs and symptoms of acute pyloric obstruction. The obstruction is usually intermittent, and the patient has intervals of good health. The natural cure may result from a separation of the polypus by torsion or strangulation of its pedicle. A fatal issue may ensue from such complications as hemorrhage, perforating ulcer, or profound debility. A gastral polypus may produce a gastroduodenal intussusception reaching as low as the upper part of the jejunum. Where gastric polypi are diagnosed by their clinical indications or recognized by the gastroscope in the region of the pyloric antrum, their removal by operation is indicated.

The Influence of the Thyroid Glands on Pregnancy and Lactation.—William M. Thompson says that the thyroid gland, situated as it is in the neck, should have any sympathy with sexual functions if it was originally the gland concerned with digestion, is, to say the least of it, extremely unlikely, but on the contrary, likely enough if it originated from a glandular organ in connection with the sexual structures of the paleostracan ancestors. There is clinical and experimental evidence of a connection with the sexual system of man and higher mammals through its secretion, in that a lack of thyroid secretion influences sexual activity adversely, that sexual activity, whether it be physiological or pathological, causes an overactivity of the thyroid, and that this hyperthyroidism constitutes an index to the toxemia of pregnancy to counteract which the thyroids raise their antitoxic protective power. There is abundant clinical evidence in support of the theory that what is termed a physiological overactivity of the thyroid is a valuable safeguard against the toxemia of pregnancy.

Procedures of Societies.

MEDICAL ASSOCIATION OF THE SOUTHWEST.

Eighth Annual Meeting, Held at Kansas City, Missouri, October 7 and 8, 1913.

The President, Dr. W. T. Woolton, of Hot Springs, Arkansas, in the Chair.

(Concluded from page 841.)

Hookworm in the Middle States.—Dr. Estill D. Holland, of Hot Springs, Arkansas, said the treatment of hookworm was not as simple, safe, or satisfactory as one might have been led to believe, but if one could start treating a patient who had had two hundred hookworms and even get half of them with each course of thymol, it would not be long before the patient would either be cured or have so few remaining that they would not cause him any inconvenience—providing he did not get a reinfection. Any physician who made more or less of a specialty of digestive troubles, as he did, or who treated digestive troubles along with a general practice, would find that the examination of the stools of his patients would explain a great many of his chronic cases. There was no way to diagnosticate a moderately severe case of hookworm except by examining the stool, and if a patient had the disease it would practically always show on such an examination.

Prolapse of the Uterus and Bladder.—Dr. J. T. Axzell, of Newton, Kansas, stated that 1, the old cystocele operation should be discarded; 2, replacement of the uterus alone was not satisfactory; 3, hysterectomy alone was worse than useless; 4, the Watkins-Wertheim operation was good and satisfactory in most cases; 5, where there was great atrophy or disease of the uterus calling for its removal, or in most severe cases the Mayo or Mont-
The High Short Incision for Cesarean Section.

—Dr. H. S. Crossen, of St. Louis, Missouri, said the high short incision in suitable cases had two distinct advantages. First there was less extensive handling of peritoneal surfaces, hence less peritoneal shock and less danger of infection from handling. Second, the incised uterus dropped away from the abdominal wall, thus preventing adhesion and firm fixation of the incised uterus to the abdominal wall, which had proved a serious matter in some cases operated in by the usual incision. The dropping away of the incised uterus from the abdominal wound was well shown in this case. The abdomen was everywhere resonant down to the pubic bone, showing that the uterus had entirely dropped away from the incision and that the intestines occupied all this region as in the normal condition. On deep palpation, the fundus uteri was felt in the pelvis.

Of course, the high incision was suitable only for clean cases, where it was permissible to open the uterus within the peritoneal cavity. When the uterus was infected, the long incision should be used so that the uterus might be turned out before being opened. Again, when there was a probability that the uterus would have to be removed, on account of a tumor or other complication, the low incision should be employed.

A Study of Epilepsy Based on One Thousand Admissions to the Kansas State Hospital for Epileptics.—Dr. M. L. Perry, of Parsons, Kansas, said to be effective systematic treatment should be begun early in the course of the disease and must be long continued. There were few cases in which individual treatment was so important. Every case of epilepsy presented distinctive features which had a bearing on its proper and scientific handling. A very large number of patients would show temporary improvement under a change of treatment. In all head injuries a careful examination should be made for fractures of the skull and for evidence of depressed bone or meningeal hemorrhage. Any of these conditions called for immediate operation as a prophylactic measure. All cases of Jacksonian epilepsy should be operated in if seen early. In long standing cases due to cortical irritation, and in chronic epilepsy from other causes little might be expected from intracranial surgery. As a routine measure a search should be made for peripheral irritations to the nervous system and if any were found appropriate remedies either surgical or medical should be instituted for their relief. The attention should not be too strongly concentrated on merely checking the convulsive attacks, but it should be borne in mind that they were only symptoms of a general nervous disease. There was no drug which of itself would effect a cure. Of all the drugs used in the treatment of epilepsy the bromide preparations were the most effective. The bromide of sodium was the most satisfactory as a usual thing. There was no advantage to be gained by combining a number of bromides. Comparatively small doses of bromides usually yielded better results on the disease as a whole than did large ones. Bromides should never be given except in proper doses determined for the individual case and where the patient was under the frequent observation of a physician. He was convinced that most of the disrepute into which the bromides had fallen in recent years was directly due to their indiscriminate and unscientific administration. Any form of medical treatment would be limited in its effectiveness unless reinforced by hygienic and dietetic regulations.

The Surgery of Jackson’s (Jonnesco’s) Membrane, Naturally a Normal Ligament, Mechanically Considered.—Dr. John E. Summers, of Omaha, Nebraska, said that most of the cases he had observed where abdominal symptoms were dependent upon defective or excessive envelopment of the bowel in a so called Jackson membrane were in people over thirty years of age, and in several they had been between fifty and sixty years of age. The intestinal wall lost its tone just as the bladder might lose its tone from the various causes that produced it. Therefore two lines of procedure might be required for the relief of intestinal stasis and the accompanying symptoms—the one to release the bowel so as to permit of freer function, the other to support the bowel, thereby increasing its muscular tone. Further experience had convinced him that the so called “white line,” which he believed to be the line of fusion of the colonic peritoneum with the parietal peritoneum after the rotation of the colon had been completed, was always demonstrable whenever the pericolic membrane could be shown, and it was the line of attachment of the pericolic membrane to the parietal peritoneum. It was demonstrated by rotating the attached hollow viscus in a direction continuous with the course of the bloodvessels and fibres of the membrane. He had called this “white line” the ligamentary attachment of the pericolic membrane to the parietal peritoneum or to the peritoneal investment of a solid viscus. Usually, when it might be deemed best to release the intestine from the investment of his ligamentary support—the pericolic membrane—it should be divided along its closest line of attachment; however, greater mobility might be obtained in some instances by dividing the membrane at its base—the “white line” when this line was short, as it frequently was in the hepatic region and in the sigmoid region, the raw space left by the division of the line in the direction with its course, could be closed by suturing at a right angle to the line of division. If the “white line” was a long one, as was sometimes the case in an extensive membrane enveloping the ascending colon, this was not practicable. When in addition to the presence of a Jackson membrane, there was a marked pitting of the hollow visceras, particularly the cecum and transverse colon, the membrane should not be divided, but some of the methods advocated by Coffey and Connell were indicated. He had found, however, in women, that a properly fitted, front-laced, straight front corset would relieve many of the symptoms that depended upon these pustes, provided proper habits of life were observed.

Gastri G and Duodenal Ulcer.—Dr. Fred H. Clark, of El Reno, Oklahoma, said gastric and duodenal ulcer might be roughly considered as a circumscribed loss of tissue on the inner wall of the
stomach or duodenum beginning with the mucous membrane and extending in depth through the various layers of the stomach wall. They might be roughly divided into two general classes, viz., acute and chronic. While other and more delicate classifications might be made, these would suffice for a brief paper. As to the causes bringing about this condition, much had been written by various authors, and the purpose of the writer would be to consider this subject rather as a clinical study than a theoretical one, so he would consider, first, the cause of an acute ulcer as some excessive toxicity or poisoning or some direct bruise, such as a fall, the patient striking with force over the region of the stomach, which might cause the sudden destruction of the tissues; and, secondly, as the cause of a chronic ulcer a lowered vitality of the tissues causing them to become weakened so that either they broke down or became so softened that they were digested by the ordinary processes of stomach digestion.

Mention had been made recently of the fact that this condition might be expected more frequently in the spring and fall than at any other time of the year. Probably more than ninety per cent, of patients suffering from gastric ulcer sought the physician for relief from what they termed indigestion. This was true, especially, in one of the cases he cited. This was caused by the fact that one of the earliest, if not the earliest, symptom of gastric ulcer was a sense of fullness in the stomach after eating. Another symptom often complained of was the desire to partake of food more frequently than usual and more or less of pain when the stomach was entirely empty. One writer had described this condition by saying that many of these patients when presenting themselves for examination would be found to have a cracker in their pocket, so they could have something to eat whenever they began to feel this discomfort which they described as a gnawing sensation in the stomach. The writer mentioned that when that condition was met with one might always make a positive diagnosis of gastric ulcer without further examination. These were the early symptoms of what was usually termed a latent ulcer and which might go on for years or which might bring on at any time a crisis which would call for heroic treatment. Hyperchlorhydria was nearly always present in this condition also. The one symptom which should always be considered serious, especially in chronic ulcer, was the presence of blood, either in the vomitus, in the water, if lavage was practiced, or in the stools; the latter could oftentimes be found only by careful microscopical examination.

With the positive diagnosis at hand, what should we say of the treatment? He quoted the opinion of the largest number of men, and with which he coincided, that the acute form of either gastric or duodenal ulcer called for medical treatment if we would avoid complications which might be briefly summarized as early hemorrhage so severe as to be fatal, adhesions which caused great discomfort and more or less danger; the complete closure of the pylorus from cicatrization, an abscess with a fistulous opening and cancer which seemed practically to always have, or at least in a very large majority of instances to have, an ulcer for its starting point. Surgery, if done early, offered excellent results for this condition in the large majority of cases.

Acute Nephritis in Children, with Special Reference to Etiology and Treatment.—Dr. H. M. McClanahan, of Omaha, Nebraska, stated that his personal observation was based upon twenty-one cases of nephritis in children ranging in age from two to twelve years, all except one having been treated in the home. All of these cases had been under his observation within the last five years. In all but three nephritis occurred as a complication of some acute infection. Five followed scarlet fever, five as a result of grippe, three an attack of tonsillitis, one within a week after diphtheria, one after chickenpox, one in the course of a severe enterocolitis, one after measles, and one occurred in a child recovering from general furunculosis. In the other three there was no history of any preceding acute infection. He was not able to secure in any of these any evidence of suppuration in any part of the body. Two of these came to his office because of the dropsy. The other one he saw at the home, the mother calling him because she noticed a peculiar shortness of the breath. In this case he suspected a preexisting scarlet, but found no clinical proof. It was a reasonable inference that acute nephritis was usually induced as a result of some general infection. It seemed probable, therefore, that some poison circulating in the blood acted as the exciting cause. Of the twenty-one patients, three had died: eighteen recovered; two died with uremic symptoms, and the other one apparently from heart failure.

Pseudomembranous Angina of the Nose and Throat.—Dr. Hugh B. Caffey, of Pittsburgh, Kansas, stated that, 1, pseudomembranous angina or Vincent's angina affecting the nose and throat resulted from an infection with the fusiform bacillus, developed a membrane, and presented clinical symptoms resembling those of diphtheria which could be positively diagnosed only by the microscopical examination of a smear taken from the seat of the disease. 2. The ordinary cultural tests would always fail to show the fusiform bacillus, hence the necessity of examining the fresh smear taken from the patient's nose or throat. 3. The disease was not limited to the tonsils and mouth, but might affect the nose independently of any other infection.

Amputation in Diabetic Gangrene.—Dr. L. H. Huffman, of Hobart, Oklahoma, reported a case of diabetic gangrene and stated that high amputations had the advantage in lessening the possibility for a return of the gangrene and a much greater chance for relieving the diabetes.

The Use of Pig Skin in Extensive Grafts.—Dr. C. S. Venable, of San Antonio, Texas, pointed out the value of pig skin for grafts where large surfaces were to be covered. A young pig of from two to six months old was selected, as at about that time the tissues were at their height of cell metabolism; and etherized. The site from which the grafts were to be taken, preferably the rump, was shaved and cleansed with soap and water, using friction with a rag, instead of a brush, as this did not contuse the epidermis. Strong antiseptics were to be avoided, as their use interfered with cell growth, and in their
stead he sponged the area with gasoline, and finally with fifty per cent. alcohol, or a one in 2,000 solution of bichloride of mercury; neither of these coagulated albumin, which was the reason for their selection. The field was now surrounded by sterile drapery, maintaining the same surgical cleanliness as though a laparotomy were to be done. To remove the graft the skin was put on the stretch with hooks or clamps in the direction in which it was to be slied, and with a thin bladed razor folded on its handle by a sawing movement, strips of epidermis were cut of the desired length and width after the manner of Thiersch. These strips were now carried on the blade to the area to be grafted and transferred by holding two fixed points with needles to the denuded area while gently withdrawing the blade, which left the graft evenly spread, when any irregularities were teased out with the needles, avoiding at all times touching the graft with the fingers or handling in any way. When sufficient grafts had been applied the rubber impregnated open mesh of Davis or a freshly prepared paraffin mesh was placed over them and held by adhesive strips beyond the edges and by multiple interrupted sutures throughout the area. This was covered with a simple dry gauze dressing, which was to be changed as often as soiled by excreted fluids. If this dressing was only from four to six thickness of gauze it would be found that the excretions were less and the area remained dry better than should a heavier dressing be applied which more effectually excluded free access of air. About the third to the sixth day the sloughing superficial epidermis was to be gently clipped away and the area exposed to the sun for half an hour or so two or three times daily. The mesh splint was removed in ten or twelve days, and thereafter the site freely exposed for as much of the time as practical. The superficial layers of squamous epithelium were going to die and slough as in any graft, so one should not be discouraged at about the fifth or the eighth day when disappointment seemed certain, as in a few more days this would change to first a creamy white surface and then a healthy pink and it would be found that the grafts had taken. He would mention here, lest one be deterred through fear of the patient becoming part swine, that this was not a source of such acquirement: the pigment soon disappeared and no bristles were grown, as the grafts were cut above the hair follicles. However, should such an unforeseen catastrophe as the advent of bristles obtain, the prognosis even then was good, as the follicles would atrophy in a very short time. He had practised this method as one of election since 1925, and had found that he was able to attain from eighty-five to one hundred per cent. of takes as against from fifty to seventy-five per cent. of takes by using heterografts or other zoogle grafts.

The Preparation of Surgical Patients and Operating Room Technic.—Dr. Merrill K. Lindsay, of Topeka, Kansas, stated that on the morning of operation tea or coffee or wine and water might be given not later than two hours prior to the anesthetic, unless the upper alimentary tract was the field of operation. Cathartics should be dispensed with two days before operation. The reason for this was that the bacterial content of the bowel was increased in direct proportion to the fluid nature of the contents and the absorption was increased by removal of the protecting mucus. Lavage of the lower bowel with either warm water or soap sods, or if this was not sufficient, soap sods and glycerin or soap sods and turpentine (soap sods eight parts, turpentine two parts) would remove the contents. This could be given on the evening preceding the morning of operation. Stirring in the white of an egg with the turpentine before mixing would prevent separation of the oil. Every patient should be thoroughly bathed with warm water and soap the night before and the skin in the region of the operation shaved. The ease of removing the hair with a depilatory was evident after using, and the following formula might be found useful:

R. Calcii caustici pulveris, ..................................... 10 parts:
Sodii sulphidi, .................................................. 3 parts:
Amyli, .......................................................... 10 parts:
Mix and add water to make a thin past and apply for five minutes. Wash off with water.

Adjacent mucous surfaces should be protected with oil before applying the paste. The skin should next be washed thoroughly with soap and water, the water and other fluids being poured, not dipped. The soap was then washed off with sterile water and the parts sponged with Stewart's and Harrington's solution.

The bladder should be empty in all cases before going to the operating room. The operating room should be made over with warm water and soap, every piece of furniture washed, special care given to the removal of dirt from overhead fixtures, and the room tightly closed from dust. The operator and his assistants should appear in the wash room in freshly laundered garments and after preparing the hands and arms in one of the approved ways should present themselves to the nurse who supplied them with a fresh sterile towel and then with gown and gloves. The application of tincture of iodine over the site of operation was not interfered with by the preparation mentioned.

Electio of Officers.—The following officers were elected for the ensuing year: President, Dr. S. S. Glasscock, of Kansas City, Kansas; vice-president from the State of Missouri, Dr. J. D. Griffith, of Kansas City; vice-president from the State of Texas, Dr. J. E. Dawson, of Vernon; vice-president from the State of Arkansas, Dr. L. R. Ellis, of Hot Springs; secretary-treasurer, Dr. F. H. Clark, of El Reno, Oklahoma.

Galveston, Texas, was selected as the place for holding the next meeting.

Letters to the Editor.

PODIATROS.

173 Lexington Avenue.
New York, October 17, 1913.
To the Editor:

Colleagues honor me with inquiries about Greek terms, sometimes—overusing my facilities to understand them and to answer, in a minute, a difficult question—by telephone. By a telephone message I was asked for the Greek word for corn and the correct term for the corrupt and ridiculous name chiropodist. The Romans, the inquirer
telephoned, called cornel clavus and physicians of the Middle Ages, cornu, from which latter the English derived corn. I interpreted him as asking for an inquiry in writing. And then I received a very long, hard, and tedious treatise, with quotations from Galen, Asclepiades, Hesios, Moschion, Dioscorides, and others who had called it helos. He said chiropodist was a corruption of cheiropeus. In all his writings, he had overlooked that the ancient Greeks employed the word tylos and tylos, that helos (the nail) was not generally used. To make matters short, I informed him that what people call a corn or doctor is in Greek tyliatos and that a chiropodist is podiatrist. I saw in vain what you look in any of the numerous medical lexicons for these two short and excellent names.

A. ROE, M.D.

THE CURE OF CHRONIC BRONCHITIS.

2914 South Vermont Avenue,
LOS ANGELES, October 19, 1913.

To the Editor:

In the December 14th and 21st issues of the New York Medical Journal, Dr. Charles H. Duncan published an article under the title of Autotherapy. In this article he stated that he was able to cure acute and subacute bronchitis within a few days, and chronic bronchitis within a few weeks. I determined to try it on myself first as a patient. My father had bronchitis for forty years, and I have had it for many years. I am now fifty-four years old. The coughing fits were coughed and expectorated at almost every night. These usually last from a half hour to forty-five minutes. I mixed one part of spumum with five parts of water and allowed it to stand for twenty-four hours with occasional agitation, and then filtered it, using a Berkefeld filter. I then had Dr. Carl Johnson, of Los Angeles, give me an injection in the lumbar region. I coughed none the next following. The second night I coughed about five minutes. On the third day I had another injection. I have had four injections altogether, each three days apart. My bronchitis was cured and I have not coughed since. I saw the symptom I have at present, if it can be called a symptom, that is, that rare occasions there is a slight effort at coughing, wholly unlike my usual cough. I can truly say that it has been magical. I do not know Doctor Duncan, and never heard of him before I read his article, but I write this merely that others who are similarly afflicted may know of this grand treatment. I shall try autotherapy out in all its various phases.

L. C. Toney, M.D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Practical Bacteriology, Blood Work, and Animal Pathology. Including Bacteriological Keys, Zoological Tables, and Explanatory Clinical Notes. By E. R. Sturtevant, A. B., Ph. G., M. D., Medical Inspector, United States Navy, Graduate of London School of Tropical Medicine, Head of Department of Tropical Medicine, United States Naval Medical School, etc. Third Edition, Revised and Enlarged, with 175 Plates and 340 Illustrations Containing 513 Figures. Philadelphia: P. Blakiston's Son & Co., 1913. Pp. xiv+408. (Price, $1.50.)

This present edition more than upholds the standard set by the previous ones and as a laboratory manual can be indeed highly recommended. It has been thoroughly revised and brought up to date and contains much valuable information clearly presented. The necessary details of technic, those which so often mean success or failure, are carefully given instead of the author taking it for granted that the reader is aware of them. Bacteriology occupies a large part of the book, but the chapters on animal parasites is particularly good. It includes the arachnoides, insects, mosquitoes, and poisonous snakes. The chapters dealing with the body fluids and organs are equally well presented, and in an appendix are given various methods for the preparation of tissues and for chemical examinations. The numerous keys and classifications add materially to the usefulness of the book.

Dr. Douglas Graham is the leader among experts in manual therapy in the United States. His advice, vast personal experience, and conscientious research among all concomitant scientific data. He enjoys the confidence of his professional colleagues in his "home town," amply justified. Hence his book, now in its fourth edition (the first appeared in 1884), faithfully represents phases of scientific evolution. It affords a masterly presentation of the subject as taught and practised in the United States.

The profession is gradually but slowly becoming aware that its neglect of hand treatments has been unwise and is resulting unfortunately—for the profession. But the testimony and labors, the urgent appeals, of reputable physicians like Dr. Graham, must soon be heeded. Among the reasons for neglect of the physical therapists is the fact that earlier exponents of massage set forth their views in so crude a form, so empirically and unconsciously, so unsupported by good scientific evidence, that small impression was made on the then unpopular breach of the student of medicine was not—and is now only rarely—taught any part of the subject by his "professors."

Medical journals are filled with glowering promises and denunciations of our present-day systems of manual therapy. Even those who, like ophthalmologists and neurologists, would secure largest good by the use of manual therapy, are rarely or never themselves expert in its actual application. They employ persons to do their work who may be as expert as they please, but who should not be so accepters of patients as a rule. The student of medicine was not—and is now only rarely—taught any part of the subject by his "professors."

The textbook before us very freely discusses the two medical branches which are mentioned on the title page. To the student of the book as a whole, it is as useful as a manual to those who wish to study a textbook of anatomy and physiology for medical students or for teachers, etc. As the subject is thoroughly treated it contains much that is unnecessary for nurses to know and which will only burden them already too much for their use. It is not intended to criticize the scientific knowledge contained in the book, as the book itself is very good, but we do wish to assert that it goes into too much detail for the use of nurses. A glossary is added to the textbook. This fact seems to endorse our opinion. It looks to us as if the
author thought that certain medical terms used in the text needed explanation. If the nurse cannot read the book with looking, his education is deficient, or the subject matter of the book is too difficult for her to understand.

The extensive application of electricity in medical practice, the various modalities employed, and the complicated apparatus required to supply the different currents necessitate special preparation on the part of those who would use it intelligently and efficiently. The greatest value of the present volume lies in the first three hundred pages which deal with the physics of electricity and with descriptions of apparatus utilized to deliver the different types of current. In view of the general excellence of this section of the book one is rather surprised at the author’s conception of an ideal static machine, viz., an eight plate Winchurst, capable of generating starks ten inches long! The apparatus for electrotherapy are, for the most part, of a mediocre standard. No attempt has been made to present more than an elementary consideration of the subject of x rays.

The Deaths of the Kings of England. By James Rae, M.A., M.D., London; Sherratt & Hughes, 1913. Pp. viii-152. (Price, 4s. 6d.)

This is a very interesting book which can be well recommended to family readers. The author has compiled, with great industry and carefulness, the death notices of the rulers of England up to William the Fourth, who died on June 20, 1837. We intentionally say the rulers as Richard Cromwell as well as his son are included in this book. We may mention here that Philip of Spain, husband of Mary I, and son of Charles I of Spain, not Charles V of Spain, as is stated on page 80 (Charles V of Germany was also King of Spain as Charles I), has also found a place in the book. We thus read that seven kings died by violence and three from senile decay. That the kings were not exempted from the ills of our race is well illustrated. Nearly every one of them was a high liver and a true representative of the period in which he lived, his humble subject being unquestionably better than his superiors.

In our issue of May 6, 1911, we mentioned the first volume of internal medicine written by Doctor Zuelzer. The book before us is well written and, while not containing anything new, gives a good review of our present knowledge of medicine. The volume belongs to a series of manuals which when finished will form a valuable textbook of practical medicine, edited by Professor Bockenheimer.

Meetings of Local Medical Societies.

Monday, November 3.—Clinical Society of the New York Throat, Nose, and Lung Hospital; German Medical Society of the City of New York; Brooklyn Hospital Club; Utica Medical Library Association; Niagara Falls Academy of Medicine; Roswell Park Medical Center, Buffalo; Albany Medical and Surgical Association; Practitioners’ Club, Newark, N. J.; Hartford Conn. Medical Society.

Tuesday, November 4.—New York Academy of Medicine (Section in Dermatology); New York Neurological Society; Clinical Society of the West Side German Dispensary and School for Clinical Medicine; Buffalo Academy of Medicine (Section in Surgery); Ogdensburg Medical Association; Oswego Academy of Medicine; Syracuse Academy of Medicine; Medical Association of Troy and Vicinity; Long Island Medical Society; Amsterdam City Medical Society; Lockport Academy of Medicine; Society of Alumni of Lebanon Hospital, New York; Bridgeport Medical Association; Johnson County, N. J., Medical Association (Jersey City).

Wednesday, November 5.—Brooklyn Society for Neurology; Society of Alumni of Bellevue Hospital, Harlem Medical Association; Bexio Medical Association; Elmira Academy of Medicine; Psychiatric Society of New York; Society of Alumni of St. John’s Hospital, Brooklyn; Schenectady Academy of Medicine.

Thursday, November 6.—New York Academy of Medicine (stated meeting); Brooklyn Surgical Society; Danville Medical Officers in Charge of the Practitioners’ Club, Buffalo; Geneva Medical Society.

Friday, November 7.—New York Academy of Medicine (Section in Surgery); New York Microscopical Society: Gynecological Society, Brooklyn; Manhattan Dermatological Society; Practitioners’ Society of New York; Corning Medical Association; Saratoga Springs Medical Society.

Saturday, November 8.—Therapeutic Club, New York.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 22, 1913:

Hasseltine, H. E., Passed Assistant Surgeon. Granted one month’s leave of absence from October 30, 1913.

Hurley, J. R., Passed Assistant Surgeon. United States, O. V. Weldon, relieved from duty at the Marine Hospital, San Francisco, Cal., and directed to report to Surgeon J. D. Long for duty in connection with plague suppressive measures in California. Passed Assistant Surgeon. United States, O. V. Weldon, relieved two months’ leave of absence from November 11, 1913.

Phelps, E. B., Professor. Directed to proceed from New York, N. Y., to Boston, Mass., and vicinity and return to New York upon completion of the duty, to advise with local health authorities regarding methods of investigating sanitary administration.

Preble, Paul, Passed Assistant Surgeon. Relieved from temporary duty in the bureau, and directed to proceed to Pittsburgh, Pa., for duty in connection with the investigations of the pollution of the Ohio River, Rucker, W. C., Assistant Surgeon General. Directed to attend a meeting of the American Electrical Railway Association to be held in Atlantic City, N. J., October 13 to 17, 1913, and deliver an address on the subject of Regula- tions on Sanitation as Related to Public Buildings.

Simpson, Frenich, Passed Assistant Surgeon. Directed to proceed immediately to Seattle, Wash., and report to Surgeon B. J. Lloyd for special temporary duty. Stiles, C. W., Professor. Directed to represent the Service at the First Annual Conference of the State, County, and Municipal Health Officers to be held in Little Rock, Ark., October 28 and 29, 1913. Thompson, L. R., Assistant Surgeon. Directed to proceed to Portsmouth, Ohio, and vicinity, to establish and operate a branch laboratory in connection with the investigations of the pollution of the Ohio River now being conducted under Passed Assistant Surgeon W. H. Frost, Trask, J. W., Assistant Surgeon General. Directed to represent the Service at the First Annual Conference of the State, County, and Municipal Health Officers, to be held in Little Rock, Ark., October 28 and 29, 1913; also to stop en route at Knoxville, Tenn., and address the Public Health Day Conference in connection with the National Conservation Exposition, October 25, 1913.

Weldon, L. O., Assistant Surgeon. Relieved from duty at the Marine Hospital, Baltimore, Md., and directed to proceed immediately to San Francisco, Cal., and report to the Surgeon General at the Marine Hospital for duty and assignment to quarters.

Wertenbaker, C. P., Surgeon. Detailed to represent the Service at the annual meeting of the State Medical Association of Virginia, to be held in Lynchburg, Va., October 21 to 24, 1913. Woodward, R. M., Surgeon.
Granted one month's leave of absence from October 4, 1913, on account of sickness.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending October 25, 1913:

Bell, C. R., First Lieutenant, Medical Corps. Ordered from Fort Bliss to Cint, Texas. Carter, H. P., First Lieutenant, Medical Corps. Ordered from duty with the 9th Infantry, Oregon, to duty with the 10th Infantry, Texas City, Texas. Casten, Charles R., First Lieutenant, Medical Corps. Relieved from duty at Fort Worden, Wash., and will proceed to Fort Columbia, Wash., relieving First Lieutenant Oswald F. Henning. Medical Reserve Corps, who, upon being thus relieved, will proceed to Presidio of Monterey, Cal., for duty.

Collins, C. C., Major, Medical Corps. Granted leave of absence for twenty days.

Connor, C. H., Captain, Medical Corps. Ordered to assume the duties of attending surgeon, New York City, in addition to present duties, during the absence of Major Russell on test ride.

Dailey, M. A., First Lieutenant, Medical Corps. Ordered to Fort Bliss upon relief from duty at Cint, Texas, by Lieutenant Bell. Davis, A. D., Captain, Medical Corps. Ordered of duty with the 22nd Infantry, twenty-five days.

Dunbar, Lee R., Captain, Medical Corps. Granted leave of absence for two months about November 8th.

Harris, H. P., First Lieutenant, Medical Corps. Ordered to duty with the S. A. Houston, Texas, for medical treatment.

Kennedy, J., First Lieutenant, Medical Reserve Corps. Ordered to Fort Morgan, Ala., to accompany Ninety-ninth Company Coast Artillery Corps to San Francisco, Cal.

Maddux, Henry C., First Lieutenant, Medical Corps. Now on leave of absence at Fort Bayard, N. M., and will report in person to the commanding officer of the general hospital at that place for temporary duty.

Michie, H. C., First Lieutenant, Medical Corps. Reported from Texas City on October 17th; assigned to duty with Field Hospital No. 3, Martagh, John A., Major, Medical Corps. Will proceed to Hot Springs, Ark., and report at the Army and Navy General Hospital for treatment.

Shockley, M. A. W., Major, Medical Corps. Granted four months' leave of absence, about December 1, 1913.

Snyder, Henry D., Lieutenant Colonel, Medical Corps. Will proceed to St. Louis, Mo., for the purpose of inspecting the medical supply depot in that city, and upon the completion of this duty will return to his proper station; the travel directed is necessary in the Army and Navy Service.

Stopseyer, W. W., Captain, Medical Corps. Granted eight days' leave of absence on completion of duty at Fort Porter. Williams, Allie W., Major, Medical Corps. Relieved from duty with the Naval Hospital Corps, and will report to the commanding general, Second Division, Texas City, Texas, for assignment to command of Field Hospital No. 3, relieving Major M. C. Usher, Medical Corps, who, upon being thus relieved will report to the commanding general, Second Division, for assignment to duty.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the two weeks ending October 25, 1913:

Blackwood, N. J., Surgeon. Detached from the Asiatic Station and ordered home to await orders.

Bogert, E. S., Medical Inspector. Detached from the Navy Yard, New York, and ordered to the Naval Medical School, Washington, D. C.

Crow, G. B., Passed Assistant Surgeon. Detached from duty at Asheville, N. C., and ordered to the Naval Medical Hospital, Washington, D. C.

Dykes, J. R., Surgeon. Detached from the Pittsburg and ordered to Mare Island Hospital for treatment.

Grieve, C. C., Surgeon. Ordered to the Naval Hospital for duty with the 3rd Infantry, sixty-days' Sergt.

Higgin, B. G., Medical Director. Placed on the retired list, October 1, 1913.

Hiden, H. B., Assistant Surgeon, Medical Reserve Corps. Ordered to the Naval Medical School, Washington, D. C.

Jenkins, H. E., Assistant Surgeon. Ordered to Disciplinary Barracks, Fort Royal, S. C.

Lowndes, C. H. T., Medical Inspector. Detached as fleet surgeon of the Asiatic Station, and ordered home to await orders.

Moran, C. L., Passed Assistant Surgeon. Detached from duty at the Boston Hospital, and ordered to Mare Island Hospital.

Murtagh, P., Surgeon. Ordered from the marine recruiting station, New York, and ordered to duty as fleet surgeon of the Asiatic Fleet.

Pleadwell, F. L., Surgeon. Detached from the Naval Medical School, Washington, D. C., and ordered to Naval Dispensary, Washington, D. C.

Porter, F. R., Passed Assistant Surgeon. Detached from the Port Royal Disciplinary Barracks, and ordered to the Brooklyn Station.

Raisin, T. W., Passed Assistant Surgeon. Detached from the Solace and ordered to the Kansas.

Smith, H. W., Passed Assistant Surgeon. Detached from the Montgomery and ordered home.

Sutton, D. G., Passed Assistant Surgeon. Detached from the Naval Academy, Annapolis, Md., and ordered to the Montgomery.

Married.

Boffin—Pells. In Philadelphia, on Tuesday, October 14th, Dr. James A. Boffin and Miss Edith Pells.

Kernan—McGinnis. In Syracuse, N. Y., on Wednesday, October 15th, Dr. Francis X. Kernan, of Freeland, Pa., and Miss Catherine A. McGinnis, of Pittsburgh, Pa., on Wednesday, October 15th.

Luhr—Wall. In Leavenworth, Kansas, on Wednesday, October 15th, Dr. Augustine C. Luhr, of St. Mary's, and Miss Gertrude May Wall.

McKinley—Robinson. In Moscow, Vermont, on Wednesday, October 15th, Dr. Arthur McKinley, of Newbury, and Miss Martha Cornelia Robinson.

Meyers—Spaulding. In Upland, N. Y., on Friday, October 17th, Dr. Harry Ahrend Meyers, of Brooklyn, and Miss Helen Spaulding.

Quigley—Moore. In Rutland, Vt., on Wednesday, October 17th, Dr. Francis E. Quigley and Miss Mary E. Moore.

Died.

Archambault. In Montreal, Canada, on Thursday, October 16th, Dr. J. L. Archambault, of Cohoes, N. Y., aged sixty-six years.

Brundage. In Goshen, N. Y., on Tuesday, October 22nd, Dr. John D. Brundage, of Wethersfield, aged seventy-nine years.

Drury. In Brooklyn, N. Y., on Monday, October 20th, Dr. George Drury, aged fifty-six years.

Hopkins. In Princeton, Ind., on Tuesday, October 7th, Dr. Joseph Neely Hopkins, of Burnt Prairie, III., aged fifty-nine years.

Keisler. In Philadelphia, on Friday, October 24th, Dr. Edwin E. Keisler.

Lucas-Championniere. In Paris, France, on Wednesday, October 22nd, Dr. Just Lucas-Championniere, aged seventy-six years.

Miller. In Leonminster, Mass., on Friday, October 17th, Dr. E. Roscoe Miller, aged fifty-four years.

Niedermeier. In Trenton, N. J., on Thursday, October 17th, Dr. William A. Niedermeier.

Spence. In Atlanta, Ga., on Sunday, October 14th, Dr. John M. Spence.

Stites. In Springfield, N. J., on Thursday, October 23d, Dr. Joseph Augustus Stites.

Toledo. In Toledo, Ohio, on Saturday, October 18th, Dr. Arthur Marks, aged thirty years.

Wadsworth. In Palmyra, New York, on Sunday, October 17th, Dr. Robert Wadsworth, aged sixty-three years.

Warren. In Attica, N. Y., on Friday, October 17th, Dr. Stephen G. Warren, aged seventy-three years.
Original Communications.

THE DANGERS AND DISADVANTAGES OF SPINAL ANESTHESIA.

By W. Wayne Babcock, M.D.,
Philadelphia,
Professor of Surgery in the Medical Department of Temple University, Surgeon to the Samaritan and Garretson Hospitals.

The innocuousness or safety of an anesthetic is a relative matter, first as dependent upon the experience and skill of the user, and second as compared to other anesthetics. No form of anesthesia has been discovered that is free from dangers or unpleasant consequences, but we may consider ether, from its almost universal employment as the standard general anesthetic, and the safety or undesirability of any other anesthetic may properly be expressed in equivalents derived from experiences with ether. At once the question arises as to the safety and morbidity of etherization. It is said that Agnew considered that one death occurred in about 28,000 etherizations; Ormsby, one in 23,224; and Juillard, one in 14,987. Gurlt, studying German statistics from 1871 to 1897, found one death in 5,000 administrations, and Bevan, of Chicago, has accepted this figure. Our own experience with ether as administered by interns in hospitals suggests a mortality of about one in 500, and recently a surgeon in an emergency hospital in the coal regions of Pennsylvania startled us by saying that he has found the mortality from ether, as administered in his community, to be over one per cent. The first impression might be that ether is much more dangerous as an anesthetic to-day than in Agnew's time, and that the dangers are progressively increasing. Those familiar with the advances made in teaching and in the administration of anesthetics will not, I believe, agree that the technic of anesthesia has universally deteriorated, and the record of 60,000 etherizations at the Mayo Clinic, without mortality, is perhaps unparalleled. We may well inquire how such divergent statistics are compiled; but without imputing their accuracy or discussing the technic employed, the important question is as to our personal and neighboring mortality from ether. From my personal guidance, statistics derived from anesthetics as they are administered for me are far more important than the results reported from Germany and France. We may admire the results obtained under special conditions by the use of ether, chloroform, or nitrous oxide, but the results appeal to us only when conditions at our command enable us to reproduce them.

I dare say that most of you can recall deaths from anesthesia. How many of these have been statistically reported? As to my own experience, I recall as a student one sudden death from chloroform anesthesia in a child brought before the clinic for a simple examination of the eyes; a second death from chloroform occurred in the office of an acquaintance as he was about to pass a urethral sound. In a college where I later taught, one death suddenly occurred under ether as an ovarian cyst was evacuated. In my personal service there was one death under ether during an operation upon an adynamic patient for perforation in typhoid. Doubtless this patient would have died despite any form of treatment, but ether precipitated the fatality. Three deaths, attributable to the anesthesia, occurred a few hours after operations for cleft palate and hare lip in infants. A fifth patient, also a child, with a cleft palate, developed pneumonia apparently from the forced pharyngeal insufflation of ether and died a week or more after operation. One old soldier, drenched with ether during a herniectomy by an untrained anesthetist also promptly developed a fatal pneumonia. A third case of fatal ether pneumonia was manifested by a severe chill shortly after etherization for a simple hysterectomy. Through an error this patient was etherized while she had a slight cold. One patient, after multiple operations including tonsillectomy, died of pulmonary edema. She became cyanosed on the operating table and died not long after being placed in bed. These do not include cases not directly attributable to the anesthetic, and represent types we have not seen after local or spinal anesthesia. As far as I know, none of these cases has been reported. Eight of these fatalities occurred in a series of about two thousand anesthetizations.

Very recently a demonstration of a new apparatus for nitrous oxide oxygen anesthesia was made in our clinic by an "expert." Of six patients anesthetized, one awoke with a hemiplegia, a second with a cortical palsy of the hand and forearm, a third with a circumflex palsy; while a fourth patient, a woman in apparent excellent condition, died from the action of the anesthetic. Nitrous oxide in any efficient combination is an exceedingly dangerous anesthetic for prolonged operations.

For comparison I have collected the experiences of several of my associates and assistants.

Doctor A., in a service in a single hospital devoted largely to abdominal surgery, had four deaths...
on the operating table which he attributes to ether and one under an assistant from ethyl chloride. A sixth patient, a robust and somewhat obese young woman, a day or so after a very simple abdominal operation a moderate fever developed, was given a cold sponge, and almost instantly became cyanotic and died within a few moments, the post mortem examination showing no lesion except an acute pulmonary edema. The cases of ether pneumonia and other complications, of which there were a number, are not recalled. This experience is embraced in a series approximating 2,500 administrations.

Doctor B. reports that he has given anesthesia by inhalation approximately 600 times. He has had one sudden death upon the operating table from pulmonary edema. The patient suffered from an advanced peritonitis following a perforation of the rectum. In a second patient an alarming edema of the larynx, lasting six hours, occurred during the performance of a minor operation. At least one fatal ether pneumonia occurred with death a few hours after etherization. He says it is probable that there were other ether pneumonias that he does not at present recall. While a medical student he saw one death from etherization; the patient, an obese woman, died suddenly while in the Trendelenburg posture. An extraneous pregnancy had been diagnosed, but the abdominal exploration was negative. In fifty estimated chloroform cases, one death he attributes to delayed chloroform poisoning, which was observed in a newborn infant. While associated for several years with a general hospital, during which time there were no more than 6,000 anesthesias, he recalls at least four additional deaths directly attributable to the anesthetic. Two occurred during the performance of circumcisions under ether at the hands of resident physicians; one during the administration of nitrous oxide oxygen by an expert who had been imported from another city especially for the purpose, and in one collapse occurred during a herniotomy, the patient dying about two hours later. In the last case the patient had been admitted in good condition, although an acute and unsuspected strangulation was found.

Doctor C. in a hospital series of 500 anesthesias, recollects one sudden death from ether during an operation for uterine fibroid. That recalls the report of a New York anesthetist, at the last meeting of the American Medical Association, of two ether deaths in a single week during operations for fibroid of the uterus. Later, in an experience of less than 500 ether anesthesias, Doctor C. has lost two patients from ether pneumonia.

Doctor D. and his associates, from their service of the past year covering less than 300 anesthetizations, report two deaths from ether. The first was a woman of thirty-six, subjected to a forceps delivery for placenta previa. The patient was in good condition, and although the operation was not rapid, there was only moderate hemorrhage during the delivery. At the beginning a few whiffs of chloroform had been employed; but this was soon discontinued on account of the fear of the anesthetist. About twenty-five ounces of ether were used, and at the completion of the delivery there was evidence of cardiac failure, and although there were some signs of life for three quarters of an hour, measures at resuscitation failed.

In the second case, an apparently robust colored woman, of thirty years, was cured for an incomplete abortion. The patient did not take the ether well, and went under the anesthesia slowly. The duration of the operation was about fifteen minutes, the anesthetic being given by a supervised student. At the completion of the operation the patient was found to be practically dead, and did not respond to the restorative measures used.

A third case of death under ether was observed in a man of seventy-eight who had been sent to another hospital for a cystoscopic examination. Open gauze was employed, the patient struggled and then collapsed, apparently from respiratory failure, about five minutes after the anesthetic had been started.

Doctor E. recalls three anesthetic deaths, not, however, under his personal care; the first a fat woman about to be subjected to a gynecological operation died under ether before being brought into the operating room; the second was a death under chloroform during amputation of the leg; and the third was a death under ethyl chloride administered for a pelvic examination.

While it is difficult to express precisely the mortality from ether, and while it must vary in those hospitals receiving only selected cases, and employing only expert anesthetists, from the average use of the drug, as it often must be used by the inexperienced and imperfectly trained, in sudden emergencies, under conditions that prevent the use of many safeguards, upon patients poorly prepared as well as those well prepared, the average mortality is, we believe, often not less than one in 500 administrations.

Mortality of Spinal Anesthesia.—From the use of spinal anesthesia it is probably easier to compute a mortality statistic, although an accurate comparison with ether cannot easily be made, for spinal anesthesia is often employed where other methods are inadvisable or not permissible. Adding the cases of my assistants and associates, we have had about 5,000 intradural injections. In four of our patients attempts at etherization had been made in other clinics. In each case the operation had to be abandoned as the patient collapsed and it was evident that complete etherization would be fatal. One was a patient with heart disease and a large uterine fibroid; the second, a patient with pelvic disease and a weak heart who was revived from the effects of the ether only after a number of hours' work; the third patient had an advanced tuberculosis of the hip and side of the pelvis, while the fourth patient had a carcinoma of the rectum. In each of these patients, without any special preoperative treatment, the operation was successfully completed under spinal anesthesia and the patients recovered. Several patients had also been refused operation at other clinics on account of advanced sepsis, old age, or other cause, yet the operation was successfully completed under intradural anesthesia. Other patients, however, while properly considered as inoperable, were subjected to the

1Each medical student is required to have given general anesthesia under supervision six times before graduation.
anesthetic and succumbed on the operating table.

The first patient, a man of about sixty years, the driver of an ash cart, and a human derelict, had gangrene of the leg and thigh following a crush from rolling off his cart while in a drunken stupor. Although nearly moribund, alypin was injected. The patient developed respiratory difficulty and died about fifteen minutes later. No operation was done.

The second patient, a man of twenty-nine, had an avulsion of the arm at the shoulder, and although shocked and pulseless, was given a high injection of stovaine. He soon developed respiratory failure, but on attempting to trim the mangled fragments, respiratory failure again developed, the patient living for six hours under continuous artificial respiration, then succumbing.

The third patient, a debilitated man of about sixty-five years, moribund from typhoid perforation and generalized peritonitis of at least twenty-four hours' standing, was injected with tropano- caine when nearly pulseless and when the extremities were cold and cyanotic. He died during the operation.

The fourth patient, an infant of twenty-one months, with advanced generalized miliary tuberculosis, tuberculous peritonitis, and a tuberculous abscess of the lung, was given a high injection of 0.015 gramme of stovaine and suddenly stopped breathing during the separation of the lobes of the lung in the search for the intrapulmonary abscess cavity.

The fifth case, an obese man of about fifty-five, with extensive intestinal gangrene and advanced diffuse purulent peritonitis associated with an enormous scrotal hernia, died during the operation.

These five patients were in a hopeless condition under any form of treatment, and four were operated upon during the period of enthusiasm that comes with the use of a new method. Three other patients died during or after operations for large empyemas.

The first patient, a man of forty-three, had an enormous empyema with extensive subcutaneous phlegmon of the chest wall. Cessation of heart action followed the rapid evacuation of the pus.

A second, a man of middle age, also suffered sudden heart failure associated with sudden escape of a large quantity of pus from the thoracic cavity. Under epinephrin and cardiac massage the heart action was resumed, but the pulmonary involvement prevented the efficient use of measures for artificial respiration. In the third patient, Miss L. E., age thirty-two, a rib was resected, and three pints of pus evacuated. The patient died the same day. With these patients artificial respiration was impracticable on account of the pulmonary lesion.

Two patients have died under operations for gall- bladder disease associated with peritonitis. Both of these patients had morphine and scopolamine as well as spinal anesthesia. The first, Mrs. K. L., age sixty, was apparently drowned by profuse, regurgitant vomiting, as the operation including a removal of the gallbladder was being completed under stovaine. There had been a previous cholecystostomy apparently followed by a more recent rupture in the peritoneal cavity. The patient had a weak heart, was obese, and had an extensive septic peritonitis of the upper abdomen. The heart action was restored under cardiac massage and epinephrin, but the Meltzer method of artificial respiration seemed absolutely inefficient, if not harmful.

The second patient had an operation upon the gallbladder performed by an assistant under 0.10 gramme of novocaine and developed respiratory failure, the early symptoms of which were probably overlooked by the resident. This patient was an obese man of about fifty years with a serious valvular lesion, and had a marked peritonitis of the upper abdomen.

Several patients had had respiratory or cardiac failure under spinal anesthesia, but have been revived. One patient, an obese colored woman, with a fibroid tumor, died undoubtedly as a result of the circulatory arrest about two days after the operation.

From upward of 5,000 injections we have had, therefore, ten deaths on the operating table, and one death after operation, in which the anesthetic was a factor.

One of the patients only, the patient with the fibroid tumor, was even in a fair condition at the time of operation. Contrasting our personal experience with ether and spinal anesthesia, both have proved to be dangerous, but spinal anesthesia no more than ether. With our present knowledge and with skilled anesthetists, many of the deaths from ether could have been avoided, and likewise most of the deaths under spinal anesthesia.

Morbidity.—This, for purposes of comparison, we have contrasted with ether. In this I am indebted to Dr. Wilmer Krusen, who kindly permitted us to study a series of his ether cases and add them to our own, and Dr. J. O. Bower, who has carefully compiled the statistics.

Nausea and Vomiting.—Apart from the frequent nausea and vomiting associated with the induction, we have found that about eighty-two per cent of patients have nausea and vomiting from etherization after their return from the operating room. Seventy-five per cent of the patients we have studied showed persistent nausea after the first twenty-four hours; sixty-one per cent, showed late vomiting occurring from the second to the fourth day.

As for spinal anesthesia, during the operation, eighteen per cent. had slight nausea and thirteen per cent. vomited. This was probably due to cerebral anemia, the anesthetic involving the upper dorsal nerve roots. Twenty-four per cent. had slight nausea and vomiting after being returned to their beds. This was either associated with an intraabdominal condition that would produce nausea or was secondary to the use of morphine or other narcotic drug. In no instance was secondary nausea or vomiting clearly attributable to the anesthetic observed. We may say that spinal anesthesia does not produce postoperative vomiting unless meningeal irritation occurs.

Albuminuria.—Despite a number of uranlyses, we have found no evidence that the intradural injection irritates the kidneys. As this is secondary to the reports of certain foreign observers, urines have been studied from time to time for several
years past. After etherization, albuminuria is not infrequent. The tolerance of patients to repeated or extensive operations upon kidneys, despite serious renal disorder, corroborates the innocuousness of intradural anesthetic as to these organs.

Backache and Postoperative Pain.—In the recent series of patients subjected to ether anesthesia, sixty-one per cent. had severe postoperative backache; while sixteen per cent. after spinal anesthesia complained of this symptom. As to the duration of postoperative pain, the average duration of incisural pain after ether was forty-eight hours as compared with twenty-nine hours after spinal anesthesia. The greater prolongation of the pain after ether is probably to be attributable to the toxemia and straining and greater disturbance from ether sickness as well as the lowered nerve resistance following the anesthetic.

The Duration of the Anesthetic Influence.—The average time required to put a patient under ether was found to be fifteen minutes; the average time required for operation forty minutes; and the average time the patient remained unconscious after leaving the operating room, one hour and fifteen minutes. The average time, therefore, that the patient is markedly under the influence of the ether was found to be two hours and ten minutes.

In spinal anesthesia the time required to produce analgesia is usually less than two minutes. The duration of the anesthetic influence is from forty-five to ninety minutes, the duration being longer when morphone and hyoscine are coincidentally employed. The brevity of the analgesia, while of advantage for the average operation, is disadvantageous in very prolonged operations, when the additional employment of ether and other anesthetics may be necessary. The emergence from the intradural analgesia is not associated with nausea, delirium, or distress as may occur from ether.

Postoperative Headache.—We have long believed postoperative headache to be the most frequent undesirable sequel of spinal anesthesia. In the recent statistical study, however, we found twenty-one per cent. of the patients after spinal anesthesia had a mild headache; while fifty per cent. of the patients after etherization complained of this symptom; the headaches, as a rule, being more severe after the ether. While we have recently seen no severe headaches after spinal anesthesia, it occurs at times in very severe form when deteriorated or imperfect solutions are employed, and indicates that the solution should be discarded.

Ocular Palsy.—In June, 1910, my colleague, Dr. Wendell Reber, reported five ocular palsies following spinal anesthesia. These had occurred in a series of 2000 injections, 1,500 of which I had personally given. Three of the patients were under my care. All occurred within a period of time of two years, and four occurred during a single year: an additional case occurring about one year later. The palsy followed the use of stovaine and tropacaine. One of the patients was a neurotic, and as there was full ocular movement with diplopia there was some question as to whether a true palsy existed. Ocular palsy has also been reported after the use of novocaine, cocaine, and other drugs.

In a second patient the conditions disappeared within twenty-four hours. These untoward effects occurred during a time when the anesthesia was producing frequent and oftentimes severe headache and pain in the back of the neck, and it is believed that the solutions were imperfect or that the anesthetic had deteriorated. Strangely enough, although about 2,000 injections have been made since this time, no other case of ocular palsy has been observed. The condition is peculiar in developing in from seven to twelve days after the injection. Usually a single abducens is involved, although at times the condition is unusual. Recovery usually follows in from a few days to several months. The period of incubation always present, and the fact that when solutions giving little evidence of meningeal irritation are employed, the palsies rarely or never occur, suggest an irritative agent exclusive of the drug, probably a microorganism.2 One of the cases occurred from the use by another department of ampoules we had discarded on account of the postoperative headaches that had followed their use.

Other Palsies.—One obese patient, suffering from a strangulated and gangrenous umbilical hernia, was given an injection while writhing upon the table. It was observed that the needle deviated to the side, and upon puncturing the dura evidence of root injury in an electric-like shock down the left leg occurred. The injection was, however, slowly given with the belief that the patient's desperate condition did not warrant a second attempt at the introduction of the needle. The gangrenous intestine was resected and there followed a violent neuritis involving the distribution of the left sciatic nerve. The condition gradually cleared so that the patient was able to walk. but had a residual foot-drop some months later. No other organic palsy due to the injection has been observed, although in a number of instances patients have attributed secondary symptoms to the anesthetic. These cases are important and often are incited by mental suggestions made by physicians or others. They frequently occur after ether, but are not attributed to the anesthetic. We have had four groups of these cases:

First Group: Cases with Symptoms Attributable to Spinal Anesthesia in Which No Intradural Injection Had Been Made.—This was exemplified in a patient referred by Doctor Keach for the incision of a mammary abscess. The patient had a severe postoperative backache and headache, which, both she and her physician at first attributed to spinal anesthesia. The patient, however, had been anesthetized by nitrous oxide and had mistaken the hypodermic injection of a narcotic for the intradural injection.

A second patient, referred by Doctor Leedom, developed meningoencephalitis two years after an appendectomy. At first spinal anesthesia was mentioned, but investigation proved that the patient had only received ether and that the condition was due to the tubercle bacillus.

Second Group: Cases in Which Functional Were Mistaken for Organic Lesions after Spinal Anesthesia.—A number of these conditions have been

---

2 In two lots of imported ampoules of solutions for spinal anesthesia we found marked microorganismal contamination.
noted, the most striking being that of a very nervous man, referred by Doctor Robin, of Wilmington, for the fixation of a loose kidney. After the operation this patient complained of extreme pain in the spine, a sore place in the throat, dulness and pressure in the back of the head, and other symptoms. The patient had marked insomnia and many nervous symptoms, and finally was sent West for nervous prostration. In Spokane, the diagnosis of embolism of the spine due to stovaine was made and the diagnosis is said to have been corroborated by several physicians and the case reported before the State society. The patient kindly submitted an x ray picture which had been taken and which was said to show a “congested condition and blood clot in the spine.” At the area indicated we found only a large shadow from the heart. The patient was placed upon iodide of potassium and gold with an explanation that it would absorb the large blood clot. Later the patient returned to Philadelphia, and came under the care of Dr. S. Weir Mitchell and Dr. John K. Mitchell. They reported that the patient had not, and never had had, an organic lesion of the spine.

A second patient, some weeks after a herniomy, developed paresis of one leg. He limped with difficulty into the hospital, where he was studied by the hospital neurologist, Dr. S. D. Ingham. The condition was found to be entirely functional and disappeared in two days. In a number of instances reports have been made by physicians and others of organic cord changes due to spinal anesthesia, but I know of no instance in which a clear relationship has been proved by an expert neurologist or by a scientific study of the patient.

The researches of Speilmeyer, Spiller, and others as to organic changes following the intradural injection of stovaine into dogs are misleading when applied to spinal anesthesia as used in human beings. The dog has about seven cubic centimetres of cerebrospinal fluid as compared with the 150 or more cubic centimetres that may be evacuated from the body of an adult man. In dogs it is very difficult to make the injection into the cavity of the arachnoid. A veterinarian who made a series of injections for me found it extremely difficult to obtain any cerebrospinal fluid from dogs and hemiplegia usually followed the injection. Anatomical differences between the cerebrospinal canals of dogs and of men, and the differences in the action of diluted and concentrated solutions of stovaine are such as to render conclusions based upon animal experimentation of no value.

Coincident Organic Disease, Independent of the Spinal Anesthesia.—An example of this is a case of carcinoma of the prostate, operated on by Doctor Steel. The patient afterward drifted to the Philadelphia Hospital, where a true progressive paraplegia at first attributed to the intradural injection was found. At autopsy, however, the cause of the paraplegia was found to be a secondary carcinoma of the spine. A second patient was brought to the operating room prepared for appendectomy. The child had been admitted to the hospital as an emergency case of acute appendicitis. I first saw the patient in the anesthetizing room, but as the symptoms were not indubitable, had him returned to the ward for further study without making the injection.

Weakness of the legs, backache, headache, and various pains are frequent after abdominal and especially after pelvic operations. We observe many instances after etherization. If the patient be nervous, and especially if she be influenced by prejudiced persons after spinal anesthesia has been administered, she will often attribute these symptoms to the drug employed. This constitutes an important objection to the use of spinal anesthesia in the neurotic, for these patients are forever searching for a hook upon which they may hang their symptoms, and spinal anesthesia often serves them well for this purpose. Simple puncture of the cord by the needle does not produce symptoms. Circumflex palsy from faulty position of the arms will not occur unless the patient be unconscious.

Technical Difficulties. Meningeal Infection.—I have seen one instance in which tuberculous meningitis developed several weeks after the resection of a tuberculous knee joint under stovaine. I know of one instance in the hands of another physician in which, after the use of a tablet of stovaine that had not been sterilized after it had left the manufacturer, the patient developed a fatal illness with symptoms suggestive of meningitis. The operation was a simple curettage of the uterus done in a private house. After the development of symptoms some cerebrospinal fluid was withdrawn which was macroscopically clear, but a microscopical examination, unfortunately, was not made. I know of no other instance of meningitis following the injection, but it is evident that the injection should only be made after the most rigid aseptic precautions have been taken.

Selection of the Patient.—The patient selected for spinal anesthesia should be in a condition to withstand a decided decrease in blood pressure and suitable for the administration of artificial respiration. Patients with marked limitation in breathing capacity or great displacement of the thoracic viscera, as from large pleural effusions, intrathoracic growths, or very advanced pulmonary disease, and those with great obesity and fatty hearts, are not safe subjects for spinal anesthesia. This does not apply to the average case of pulmonary tuberculosis. Spinal anesthesia is also dangerous in a patient whose central nervous system is greatly depressed through traumatic shock, hemorrhage, or advanced sepsis or toxemia. Patients of these types are often selected by the novice, while spinal anesthesia, if used at all, should be given only with the greatest care and by an expert. By fixing a cannula into a vein previous to operation and by the graduated intravenous use of ephinephrinal saline, the depressing influence of the analgesic may be combated. In this way we have found it possible to tide a pulseless and apparently moribund patient through a serious operation. Spinal anesthesia should not be used in these advanced cases when local anesthesia or a few whiffs of ether will suffice for the operative procedure. For thoracic and gall bladder operations upon the desperately ill patient, local anesthesia should, as a rule, be selected. While physicians are never more forcibly taught the sin of procrastination than by an operation upon
their nearly moribund patients from generalized peritonitis, we shall not contend against those who prefer to have these unfortunate patients die under the Ochsner treatment.

Position of the Patient.—In rare instances a patient is unable to breathe in a recumbent position. For such a patient one should only use a solution of high specific gravity, or better, substitute local anesthesia. One surgeon has reported to me a case of tuberculous peritonitis with such enormous effusion that the patient could not lie down. Eight centigrammes of low specific gravity were injected. The patient was left in the sitting posture, the solution ascended, and, as would be expected, respiratory failure and death promptly followed. In such a case we would probably select local anesthesia, or give, not to exceed, 4.5 centigrammes of stovaine in a solution of high specific gravity. As a rule, the patient should not be raised to a sitting posture until one half hour has elapsed after the introduction of the anesthetic. In several instances we have observed temporary syncope from too early elevation of the patient.

Movement of the Patient.—Care also is necessary in moving and in carrying the patient immediately after the injection for fear of a dangerous upward diffusion of the drug. Without constant watchfulness the orderly or resident will lift or carry the patient with the head and shoulders raised, as the patient is being transferred to the operating room on a different floor in a hospital by means of an elevator. Immediately after the transference the patient, a very weak and debilitated man, suddenly collapsed and died. Although in this case there is evidence that death resulted from other causes, it is our opinion that if the injection cannot be made upon the operating table, and if the patient cannot be kept reasonably quiet and under expert supervision for at least thirty minutes after the injection, the use of spinal anesthesia is unjustifiable. It is likewise of great importance that the patient’s pulse, respiration, and general condition be constantly watched during the first thirty minutes of the analgesia. Respiratory and cardiac failure are to be feared when a debilitated patient is being watched by an inattentive assistant so careless as to not observe the premonitory signs of danger, or to institute the proper anticipatory treatment.

Influence of Repeated Injections.—Many of our patients have had spinal anesthesia induced a number of times. One patient at present in the hospital has had spinal anesthesia eleven times, over a period of several years. A number of patients have had several injections for one operation or with a few days interval. In none of these patients has any secondary evidence of cord injury been apparent, and in none of these patients has any secondary organic lesion attributable to the injection been observed.

Breaking of the Needle.—Several years ago Litauer (Centralblatt für Gynäkologie) reported two cases in which the cannula had been fractured in the patient’s back. In one instance three centimetres of the distal end of the tube was left in the patient’s spine, yet no symptoms had followed at the end of two years. In the second, the cannula was immediately removed without ill effects. In one case I had the same mishap while using a very delicate highly tempered steel needle in a young child; the child suddenly straightened the back as the needle was introduced, the vertebral lamina came together, breaking the needle. I at once cut down through the tract of the needle puncture and found the end in the interspinous ligament. It was withdrawn and the operation of herniotomy completed without secondary symptoms. Some months ago I was handed a communication from a physician in a western State against whom legal action had been brought for a fracture of a cannula during a lumbar puncture in a child with spinal meningitis. No untoward symptoms had followed the accident. These mishaps emphasize the importance of employing gold or platinum needles. Several times have I had patients bend needles by movements during the introduction, but I know of no instance in which a platinum needle has broken beneath the skin.

Consciousness of the Patient.—The conscious state during the progress of the operation is, with certain patients, very objectionable. With spinal anesthesia this may be obviated by administering sufficient morphine, scopolamine, or other narcotic previous to the operation to produce unconsciousness. The use of these drugs undoubtedly increases the danger of respiratory and cardiac failure, particularly in patients who are already adynamic and toxic. In children narcosis is not as satisfactory, but in them consciousness is usually less objectionable than in adults.

Morale of the Operating Room.—Ether has the advantage of rendering the patient completely oblivious to all that transpires in the operating room. The conversation of those present is unheard, the behavior of the operator and the assistants under the stress of the operation is not perceived by the patient, and the lack of a systematic routine is not observed. Under nitrous oxide anesthesia or nitrous oxide oxygen anesthesia the patient may hear things that are said and thus acquire a fixed prejudice against the operator; and likewise, under spinal anesthesia, if the patient be not thoroughly narcotized, the method has decided disadvantages to the surgeon or his assistants who lack proper poise in the meeting of emergencies.

Inability to Properly Introduce the Solution.—In over 3,000 injections, I once failed in a kyphotic dwarf to enter the spinal canal. In the first patient upon whom I tried spinal anesthesia I likewise failed to introduce the needle, but on a later occasion was successful. In two instances, although the needle entered the spinal canal, no fluid was obtained and anesthesia was not produced. In one other case, cerebrospinal fluid was obtained, but despite repeated injections no anesthesia resulted, probably because the fluid was extradural. Perhaps in five per cent. of the patients the injection must either be repeated, another injection given, or another anesthetic employed. This may be due to the imperfect introduction of the needle through the dura, the leakage of fluid, an insufficient dose, or a defect in the solution.

Dose.—Unfortunately, most of the substances used for spinal anesthesia are under proprietary control and have not been rigidly standardized. Ap-
parently, different samples show variations in activity amounting even to thirty per cent. As a ten per cent. increase in the dose may be dangerous, these variations necessitate great care in the employment of every new lot of the anesthetic. For example, at times we find 0.04 gramme a proper dose of stovaine, again 0.06 gramme. The dose must be accurate, for once given it cannot be recalled. In one instance in Philadelphia, an inexperienced operator gave 0.4 gramme of stovaine—eight times the normal dose. The patient promptly died.

This case was reported in the literature, but not the dose employed.

**CONCLUSIONS.**

In our personal experience ether and spinal anesthesia have been about equally dangerous, ether from exigencies compelling a profound narcosis or an imperfectly trained anesthetist; spinal anesthesia from an unwise selection of patients and an imperfect knowledge as to the physiological action of the drug. With careless or unskilled use, spinal anesthesia is doubtless much more dangerous than ether.

The morbidity of spinal anesthesia as expressed by nausea, vomiting, headache, backache, postoperative pain, and albuminuria is less than that from ether.

Ocular palsy may result from spinal anesthesia where contaminated or deteriorated solutions are used. A lateral deviation of the needle with injury to a nerve root may be followed by severe neuritis and secondary palsy.

Secondary degeneration of the spinal cord from the chemical action of stovaine, properly introduced in human beings, for purposes of spinal anesthesia is doubted.

Functional or neurotic symptoms occur after spinal anesthesia as they do after etherization, and may, to the annoyance of the surgeon, be attributed by the patient to the injection. If a steel needle be used it may be broken under the skin during the injection.

Danger symptoms may follow if the patient be moved immediately after the injection or if the proper posture to prevent the anesthetic from reaching the upper nerve roots be not maintained for at least one half hour after the injection.

Repeated intradural injections seem to be harmless.

Spinal anesthesia is dangerous in circulatory atension, conditions greatly depressing the respiratory centres, and shock, collapse, advanced myocardial disease, and large intrathoracic effusions. It is more dangerous for operations upon the upper abdomen than those upon the lower. It does not obviate the danger of sudden cardiac arrest in operations for large uterine fibroids.

The newer methods of anesthesia, including spinal anesthesia, nitrous oxide oxygen, intravenous anesthesia should have their use restricted to selected patients by those who have properly qualified themselves.

If the patient cannot be properly watched for one hour after the injection, if the operator does not understand the dose and mode of diffusion of the drug, or if he is unprepared to meet emergencies, then spinal anesthesia should not be employed.

For general indiscriminate use ether remains the standard anesthetic despite its many drawbacks.

**PREVENTIVE MEDICINE AND THE FAMILY DOCTOR.**

**By Adam H. Wright, B. A., M. D., M. R. C. S. (Eng.).**

Professor Obstetrics, University of Toronto.

We are told that the general practitioner has disappeared, and that this is the period of specialists. While we may think that the first part of this statement is not correct, we have to acknowledge that a process of evolution is taking place with respect to the specialist and the family doctor. The growing importance of specialization is so generally recognized that the needs of the general practitioner are now being overlooked in certain quarters. Surely we should not ignore the fact that over ninety per cent. of the doctors in North America and Great Britain are general practitioners. This ratio is likely to continue for many years to come, probably forever.

Many of us think therefore that the family doctor in the near future will become as important a member of the profession as the most scientific specialist. We believe, however, that the general practitioner and the specialist will work together, and thus accomplish the greatest possible good in the interests of suffering humanity. Let us consider the family doctor from the standpoint of preventive medicine.

In speaking of preventive measures in routine, general practice, it seems suitable to commence with the subject of obstetrics; because, in that department, preventive measures, so far as I know, were first generally observed. For many years obstetricians, including the majority of general practitioners, have realized the importance of keeping women under very careful observation during the whole or the greater part of pregnancy. Our object is, to put the matter very plainly, to prevent our patients from getting sick. We desire especially to prevent toxemia and its results, such as pernicious vomiting, acute yellow atrophy, and eclampsia. This is of course only a small part of the story, but it seems sufficient to illustrate our point.

Let us now consider preventive treatment in connection with the young babe. It is unnecessary to name the many dangers to which it is exposed. The doctor of the past has been altogether too indifferent about the proper care of the baby. When he is informed that the little one has been fretful, he too often makes no examination, and simply advises a dose of castor oil, or something of that sort. The doctor should realize that the care of a baby is really a serious problem. With this in his mind, he should supervise. Proper supervision requires no great brain power, but there is a supreme necessity for
looking after details. Among these details are cleanliness, suitable dressing, care during the day, care during the night, proper feeding, care of the mouth during teething, and many other details which need not be mentioned now. These recommendations mean frequent visits, careful inspection at each visit, and minute instructions, preferably written in the majority of cases. Our object should be to prevent disease. Mothers more than fathers are now realizing the value of preventive measures, and they are endeavoring to educate their husbands. We believe that even now a large portion of the public would prefer to pay the doctors for keeping their children well, instead of waiting until they get sick before asking for professional treatment.

We do not know that there is any age at which the family doctor should cease to exercise a careful supervision over children. We may, however, refer to one very important matter. It is generally understood that the period when a girl is growing into womanhood is one of the most critical in her life. The family doctor knows this; but too frequently does not take the active interest in her that he should. Unfortunately, many mothers think that slight disturbances, or small variations from perfect health are usual and that the girl will “grow out of them” before, or as she becomes a woman. In certain schools, well conducted in a general way, a girl is sometimes allowed to get seriously ill before her mother or the doctor is notified. No girl should be allowed to get sick, in the ordinary sense of the word, before she is looked after. Our aim should be to prevent the illness. In such a case we should consider clothing, food, regulation of the bowels, ventilation, exercise, and schooling. To prevent serious illness it is sometimes advisable to remove the girl from school for a term. The mother is anxious to have her daughter get a good education, and frequently objects to any “break” in her studies. The father is generally worse and is inclined to despise a “doctor’s fads.” He will wait until his daughter gets nervous prostration; and then, with his eyes properly filled with tears, will send her to a sanatorium for six or twelve months. However, in such a case before serious damage is done, the physician may explain the matter to the mother, and show her that good health is the all important thing for her child; and, if he convinces her, he can generally accomplish his object. Perhaps you remember what Brown said to his friend: “See here, Jones, why don’t you brace up and show your wife who is running your house.” “It is quite unnecessary,” replied Jones, “she knows.” If you get the mother on your side, you can usually carry your point.

Let us refer to another time in a woman’s life, the consideration of which will help to illustrate the trend of this paper. It is well known that the menopause is a critical period. It is thought by some that both doctors and patients are inclined to get too “fussy” on this subject. That may be true to a certain extent, but we believe that every doubtful case should be carefully investigated. In many cases we can, by simple preventive treatment and judicious advice, accomplish great good without giving much medicine. In such cases we should, of course, always consider the possibility of malignant disease. When in doubt one should get the help of a specialist, as soon as possible.

This leads up to the consideration of diagnosis, which is exceedingly important in connection with preventive treatment. Let us go back to the patient we were treating during pregnancy. There may be doubt as to the condition. If there is ectopic gestation, it is exceedingly important that the family doctor should be able to make a diagnosis. His ability to do so is quite as important, if not more so, than similar ability in the specialist. In extrauterine pregnancy he should recognize the condition before rupture takes place. Some of the saddest tragedies I have known have resulted from a nonrecognition of this condition in time to prevent disaster. Without giving any other examples we have only to say that the family doctor should be an allround good diagnostician.

Let us glance at the great field of abdominal diseases. How much can we accomplish as to them by preventive measures? No detailed attempt will now be made to answer this question. But let us think of certain possibilities. Supposing our general practitioners took charge of all the children in Canada aged six, and they and their successors looked after them continuously until they reached the age of twenty-six (or more if you like)—taught them how to eat, how to drink, how to sleep, how to dress, how to work, how to rest, how to play—in short, how to live—what would be the result? We don’t know, but we have an idea they would to a wonderful extent curtail the work of all kinds of specialists and, in fact, put a vast number of them “out of business.”

In the meantime we must recognize the fact that specialization is at present a necessity, and that the specialists of to-day are doing the grandest work, in various departments, that the world has ever known. We acknowledge this, although we have to note, with regret, that some of our latest specialists, who have been rapidly manufactured without any knowledge of general practice, are rather narrow and often unsafe in some respects. Most of our specialists in Canada were general practitioners first, and specialists second, and, on the whole, are a body of men we admire very much, even though it be our main object to limit their work as much as possible.

We are justly proud of our advances in matters pertaining to public health; but we want the family doctor to go far beyond the science of hygiene as it is generally understood. It is not enough to learn how to milk a cow according to Doctor Hastings’s most improved methods, to chlorinate dirty water, to open windows, to dig ditches, to construct sewers, to burn refuse, to select the proper kind of fish, flesh, fowl, etc. We recognize the vast importance of all these things, but we know pure milk kills many babies; we know that pure food kills many children and adults. We find, for instance, that a robust vigorous young athlete who is a “good feeder” frequently dies young, while the poor dyspeptic, who has a capacity for eating about equal to that of a canary bird, never dies—or takes such a long time to die, that we are apt to lose interest in his existence and scarcely notice his final de-
BEHAN: SURGERY IN THE SERVIAN-BULGARIAN WAR.

November 8, 1913.

Surgical Experiences During the Last Servian-Bulgarian War.

By Richard J. Behan, M.D.,
Surgeon, Fourth Reserve Hospital, Nish, Servia.

It was on the afternoon of July 7, 1913, in Berlin, that I received a telegram (two days on the way) from Mr. Sommers, the American Consul at Belgrade. In this he asked if I and two others vouched for as capable surgeons could immediately leave for Servia. At twelve o'clock the same evening, in company with Doctor Rosenkranz, of Los Angeles (who had also received a similar telegram) and Doctor McKinney, of Chicago, I was on the way. Owing to the distance from Berlin, we did not arrive till ten o'clock on Wednesday. While in Budapest the previous evening, in the company of Mr. Mallet the acting American Consul there, we heard that the Bulgars were advancing into Servia in all directions and that as the Neue Freie Presse stated, the struggle would shortly be over. This, of course, was not welcome news to us, because even then we felt somewhat partisan to, and sympathetic with, the people whom we were going to serve. However, we found later that much of what we had heard was nothing but the purest fiction.

Shortly after arriving in Belgrade, we called on Mr. Sommers and went with him to interview Colonel Sondermeyer, the bureaucratic head of the Servian medical department. We were kindly received by him, and made our arrangements with a major adjutant. We were given the choice of either remaining in Belgrade, where we would receive a hospital, or of going to the front. It was asked of us as a great favor that we go to the front, as there the need for physicians was most urgent.

We immediately consented and were assigned to Nish, a town about 200 kilometres (160 miles) from Belgrade, fifty kilometres (forty miles) from Pirot, where at this time fighting was quite severe. We were promised and later received a salary of 400 francs monthly, our traveling expenses (to and return), which amounted to about 200 francs, and our board and lodging during the time of our active service.

The next morning we started for our station. The train left at 7:50 a.m., and although Nish is only about 160 miles distant from Belgrade, we...
were on the journey till one o’clock the following morning, at least seventeen hours. The reason for our slow progress was that everywhere along the route soldiers were either embarking or detraining. Every station was thronged with soldiers and people all eager for war news. The man with the newspaper was at a premium and was always the centre of a group. In many cases we saw wounded soldiers, returning from the front, the centre of a crowd who were listening with open mouths and glistening eyes to the tales recited by these soldier heroes. At Stalitz (Stolac) we were compelled to change to a military train, as the passenger trains did not run beyond this point. We arrived here at 2.30 p.m. and waited four hours till the next military train going to Nish arrived. During this time several train loads of wounded passed us on the way to Belgrade on to Krajugevac.

On our way we also made the acquaintance of several correspondents who were also going to the front. On this journey we were treated by the Servians with the greatest courtesy. All the way we occupied first class compartments. On our arrival at Nish we were met by Doctor Jablons, an American surgeon, of Brooklyn, N. Y., who had been engaged as bacteriologist at Nish since the beginning of April. We were safely in our hotel at 1.30 a.m., and thus ended the first stage of our journey.

The next morning we were given the choice of hospitals and selected the Fourth Reserve, which formerly had been a cavalry barracks. It consisted of three large buildings. Two of the buildings had accommodations for about 280 patients apiece.

The third or central building had accommodation for about 500, so that the entire hospital accommodation was about 1,060 patients. However, there was a lack of beds, bed accommodation being present for only about 800 patients. The remainder had no beds, but slept on straw mattresses on the floor. However, it was only the Bulgarian patients who were forced to this extreme. Every Servian had a bed of his own. This discrimination against the Bulgars began, however, only after the atrocities committed by their fellow Bulgars at Kajac had become known.

Doctor Rosenkranz and I were assigned to the first pavilion with about 270 patients. Doctor McKinney remained with the Servian medical officer who had charge of the middle pavilion for a few days, when he was assigned to the third pavilion. The fourth pavilion was later under the nominal charge of Dr. Richard Bier, of Berlin, who, however, never entirely resigned his position at the country hospital where he was in charge. After a short time he voluntarily gave up the fourth pavilion to the care of the surgeons who were there in charge. The work was severe. It meant labor from 8 a.m. until 1 p.m., then a pause till 3 p.m., and again work till 8 p.m. There was such a lack of instruments that the simplest operation could not be performed, all our dressing room (at this time we had no operating room) afforded was a table, plenty of sterile bandages, a few forceps, a knife, a pair of scissors, and solutions of alcohol and benzine, with appropriate trays.

At first our assistants were untrained soldiers, but with remarkable rapidity they picked up the
SKILLERN: FRACTURE OF PELVIS IN CHILD.

907

November 8, 1913.

rudiments of surgical nursing, so that in a week they became very proficient. The proficiency is indicated by the fact that of the hundreds of cases dressed by them not one case of secondary infection occurred. This is a record surely to be proud of even by a well equipped hospital with a trained hospital staff.

Discouraged by the lack of all the necessary essentials for proper care of the wounded, I telephoned to Mr. Sommers, the American Consul at Belgrade, and inquired if it were at all possible to collect any money or in any other way to acquire operating room equipment. He sent telegrams to the American Consuls at Paris, Berlin, and Baden-Baden, also to the New York Herald. Inside of twenty-four hours he had word from Mr. Pool, the assistant consul at Berlin, that he had collected $400, most of it coming from the treasury of the American Women’s Club of Berlin.

This money was expended for instruments, which were conveyed to us by the kindness of Frau von Oettingen, the wife of one of the German surgeons employed in Nish. An operating room was now erected in the fourth pavilion, and it was no longer necessary for us to send our operative cases to other hospitals. However, even with the great number of patients (over 2,000) who passed through our hands in the six weeks we were there, the necessity for major operations came relatively seldom.

The wounded were of all types. Of 177 cases selected at random, we had five scalp wounds—of these one was a very severe laceration; two skull injuries with fracture; eight face injuries, one with destruction of the eye, three with fracture of the lower jaw, one with persisting parotid fistula; five neck wounds; seventeen with chest wounds, in whom empyema developed in five with subsequent operation; six with abdominal wounds, all recovered without operation; sixteen upper arm wounds with four fractures of the humerus and one of the clavicle; twenty-one wounds of the forearm with two fractures of both radius and ulna and one fracture of the radius; twenty-two wounds of the hands; twenty-seven wounds of the thigh with two fractures of the femur; twenty-four wounds of the leg with four fractures of the tibia; and twenty-four wounds of the foot. Most of the cases except the fractures and infected cases were dis-charged in about a week or ten days. Of the 177 soldiers, fourteen had been wounded in more places, and twenty-four were more or less severely infected. The mildly infected cases, in which the wounds were superficial, were not counted.

Of the 154 soldiers of whom we have records, fifty-six were wounded by shrapnel, ninety-four by bullets, two by grenades, and two by bayonet. We also ran across evidences of the cruelty of the Bulgars, in that we had in our hospital the only four survivors of a body of thirty men of the Fourth Reserve, whom the Bulgars after capturing grouped into a solid mass, then forming a ring about them with fixed bayonets, they danced around the cowering mass in the centre, advancing and retreating from them. Each time that they approached they prodded them one or more times with their bayonets. After the dance was over the writhing human mound in the centre was left to its own anguish and distress, for from out of that bleeding mound how, thought the Bulgars, was it possible for one poor mangled soul to emerge alive. So they left it. But that night the Servians, eager to avenge the insults to their women and their manhood, returned, captured the village, and received the heritage of the mangled companions. Of the thirty only four were found alive. Then woe to the Bulgar who fell into the hands of the enraged troops, who got beyond control of the officers and gave no quarter to those whose ill luck it was to fall into their hands. The four survivors of the massacre were sent to us. Of the four, three had been castrated. One of these died the same night. Of the three others, one who had a bayonet wound of the back penetrating into the rectum and the pelvis died in two days. The other two recovered. It was after this occurrence that the Servian soldiers developed their great antipathy to the Bulgars.

After the peace was concluded we remained about a week. In this time we sent home all who could possibly go, and as at the end of this period there were only eighty patients in our hospital, it was decided to close it and to transfer the patients to the military hospital at Chela Kula. Throughout the entire time of our stay in Nish we were the constant recipients of favors from the American Consul, Mr. Sommers, who even saw to it that we were plentifully supplied with American newspapers. We were also visited by him and Senator Young, of Iowa. Especially must we thank those good Americans who so cheerfully gave of their money in order that we might be enabled properly to carry on our work.

A CASE OF FRACTURE OF PELVIS IN A CHILD AGED SEVEN.

By P. G. Skillern, Jr., M. D., Philadelphia.

Packard (International Encyclopedia of Surgery, 1884, IV, p. 91) says: "Fracture of the pelvis is almost unknown in children. The youngest patient I remember to have treated for such an injury was sixteen years old. Bryant, however, mentions two
cases seen by him in children, and a few others are upon record.7 The following patient was brought to me for examination by Dr. T. W. Buschmann in the Surgical Outpatient Clinic of the University Hospital, service of Dr. B. A. Thomas, October 16, 1913:

E. A., male, white, aged seven years, while at play the day previously, was struck by an empty limebox over the pubic region. Examination revealed ecchymosis between the anterior superior iliac spines and the symphysis pubis and "wincing" tenderness over the osa pubes. There were no signs of injury to the bladder. The child could walk without difficulty, and complained of nothing except tenderness on palpation. Bimanual rectoabdominal palpation, in which the pubic arch was sandwiched between the fingers of the examining hands, again elicited "wincing" tenderness but no unevenness on the surfaces of the bones and no crepitus, no preternatural mobility. There was a small hematoma in the space of Retzius. Sigmoid (Fig. 1), taken by Dr. H. K. Pancost, showed bilateral symmetrical oblique lines involving bodies of pubic bones, each starting at upper part of symphysis and extending downward and outward to reach margin of thyroid foramen 1.5 centimetres below the pubic crest. On the right side this fracture line passed across the lower part of the thyroid foramen to involve the body of the ischium just above its junction with the tuberosity. On the left side

organ in childhood) or stretch the triangular liga-
ment and rupture the urethra. Had not the clues of ecchymosis and "wincing" tenderness aroused suspicion of fracture sufficiently to resort to the x rays, the fractures doubtless would have been overlooked and treated as a contusion.

241 South Thirteenth Street.

INFANTILE PARALYSIS
Affecting the Lower Extremities: Its Surgical Treatment and Possibilities of Cure.*

By E. P. Magruder, A. M., M. D.,
Clinical Professor of Surgery, George Town University; Associate Surgeon, Emergency Hospital.

INTRODUCTION.
The attention of the entire medical world has of late years been directed to the problem of infantile paralysis. And little wonder for, rickets excepted, it is the most prolific source of deformity. The clinical picture of an onset so mild, quickly followed by a paralysis so complete, is simply appalling. The important work of Heine, Charcot, Strümpel, Medin, the terrible Swedish epidemic of 1890, followed by those in Germany, France, Italy, and the United States, have held the interest of the profession unabated, while the Swedish epidemic of 1895 inspired the exhaustive studies of Wickman, who demonstrated beyond peradventure the contagious character of the malady. In 1900, Landsteiner and Popper first produced the condition experimentally in monkeys, which experiment was shortly repeated by Flexner and Lewis. In the same year, almost at the same time, New York, Paris, Vienna—through Flexner and Lewis, Landsteiner and Le- vaditi, Leiner and von Wiesner, respectively—contended for the honor of having transferred the condition from one monkey to another. Finally, Flexner and Noguchi only a few weeks ago, recovered pure cultures of the organism producing the disease. While the isolation of this organism is of great value, the crippled condition of the patient is the paramount issue of the attack, and to this aspect of the subject it is the purpose of this paper to invite your attention.

ETIOLOGY AND PATHOLOGY.
It is now definitely determined that anterior poliomyelitis is due to the "globular or globoid bodies averaging in young cultures 0.15 to 0.3 micron in size." While it is claimed that the bite of the stable fly directly transmits the disease, it is more frequently acquired through the nares. The upper nasal cavities communicate directly with the meninges along the lymphatic tracts which pass outward with the filaments of the olfactory nerves. Thus the organisms enter the body through the perivascular lymph spaces of the bloodvessels of the leptomeninges. This lymph is in communication with the cerebrospinal fluid. The first change observed in the nervous system is the hyperemia and collection of mononuclear cells, in the lymph spaces surrounding the vessels. This

---

7Comparison of this diagram with that of a normal pelvis of same age proved the lines of fracture were not epiphyseal lines.
obstructs the circulation, causing hemorrhage and edema; hence, these three elements, cellular exudate, hemorrhage, and edema, constitute the nervous system's primary reaction to the invading organism. The blood supply of the spinal cord is greatest at the cervical and lumbar enlargements, and here the nervous lesions are most conspicuous, and for the same reason the anterior horns of the gray matter are more directly affected than the posterior horns. It is true that the cells may be affected by a direct toxic action of the products of the organism, and that anemia following constriction of the vessels may play a prominent part, so that any one or all of the factors—exudate, hemorrhage, edema, toxemia, and anemia—may affect the cells themselves, and by pressure or anemia cause the cells to degenerate. If the hemorrhage and exudate are early absorbed, the cells recover and function is renewed. Their long persistence on the other hand, may result in complete necrosis of the nerve cells. While its effects are more or less general, upon the nervous system, the toxine has a predilection, causing paralysis or death through destruction of the respiratory nerve cells.

THE PARALYSES.

At necropsy the extent of involvement of the gray matter of the cord may be out of all proportion to that represented by the muscular paralysis. The white matter may likewise be involved without any apparent symptom. Fortunately the nerve fibres supplying most of the muscles spring from different levels of the cord, hence the functional activity of the muscles is safeguarded. The extreme irregularity of distribution of the paralysis affecting here individuals, there groups, and again skipping muscles altogether, is due to the lesion being within the cord as distinct from that within the periphery.

A certain number of paralyses are of transient character, lasting for a few days or a few weeks. The nerve cells have not been destroyed, but have suffered temporary, yet profound toxemia, with a resultant disturbance of function, or as the result of pressure from hemorrhage, edema, or exudate. A certain number are completely and permanently paralyzed, in which there is an actual destruction of all the nerve cells from which the fibres supplying the affected muscles arise. A third group of cases represents a condition of weakness with no actual paralysis. The exudate or edema or hemorrhage through pressure has interfered with the nerve cell function without actual destruction of cells or, at most, with destruction of but few. Bing is authority for the statement, "Anterior group lesions . . . unless very extensive, merely weaken and do not completely paralyze the muscles, owing to the fact that as a rule, the muscle is innervated from several roots."

In T. A. Groover's 868 cases, eighty-five per cent. were affected in one or both legs. The paralysis is limited to the legs alone in nearly one half of all cases. The lesion found is in the lumbar enlargement of the cord, particularly that segment which lies between the first lumbar and second sacral vertebrae. We may find one leg, both legs, or a particular muscle or group of muscles, involved. The muscles in the leg most frequently affected are the anterior group, the peronei, the flexors of the foot, and the extensors of the toes. Of the muscles of the thigh, the quadriceps extensor femoris is the most frequent victim. There is a marked difference of temperature between the normal and paralyzed limbs, the latter being quite cool to the touch. The proximal group of muscles is more liable to paralysis than the distal; the latter group recovers more quickly, too, after paralysis.

In the process of repair the surviving nerve cells may assume new functions, and surviving muscles

![Fig. 1.—Showing head of bone partially without the acetabulum, and apparent lengthening of femur of affected limb. Radiograph taken before operation by Dr. T. A. Groover.]

may assume in part the action of those which have been injured. Recovery in the chronic conditions is very slow, and treatment should be carefully and conscientiously carried out. Mechanical supports should not be resorted to too early at the expense of undeveloped by developing muscles. Delay on the other hand of the surgical treatment may result in deformities of much greater difficulty for correction. Cooperation between internist and surgeon is the solution to this question.

CASE.

In the case to be presented, I am under great obligations to Mr. Jones, of Liverpool, for the suggestions of his splendid work, which I had the pleasure to observe while there about eighteen months ago, especially as regards tendon transplantation.
and the open air treatment of his cases. Many of his views are herewith incorporated. I must differ with him, however, as regards the value of long delay for an arthrodesis, when one can use the time-saving, equally effective, and far simpler method of double fixation. My case follows:

Case. L. J., male, aged three years, of Prince George’s County, Md. Family history, negative. Father and mother, two sisters, and a brother, alive and enjoying good health. None of these had experienced any illness similar to that of the patient, though there were other cases, I am told, occurring at the same time in that neighborhood. There are no evidences whatever of syphilis in the parents. Previous history: The child was breast fed, enjoyed excellent health, was quite strong and active till nearly six months of age. Present illness: When nearly six months of age, he was taken suddenly ill, with restlessness, fever, and great irritability. He apparently desired to be let alone. Any motion in the attempt to lift him would cause him to cry out with pain. In a few days the mother noticed that he was quite unable to move his right leg, which lay limp and lifeless. After some weeks the child appeared normal again, except that its right lower extremity seemed completely paralyzed and remained so for two years. In May last, the child was referred to me. Physical examination: The child was fairly well nourished and normal in appearance except as regards the entire right lower extremity, which was in a state of apparently complete flaccid paralysis. The thigh hung limp from the hip joint, with slight flexion at the knee. There was marked difference in the measurements of the two thighs, legs, and feet. The pointed toe of the right foot was typical. The reflexes were normal in the left lower ex-

tremity, while on the right, knee jerk, Achilles, Babinski, and Kernig’s signs were all absent. With the exception of the slight tonicity of the biceps, loss of power seemed complete. If the child was made to stand upon the sound leg, there was marked external rotation of the right thigh, elevation and abduction of the leg and foot. The capsule of the hip joint was quite relaxed, and the head of the femur rotated freely, partially without the acetabulum. The arc of rotation described by the trochanter was very much exaggerated as compared with that of the sound side. The flaccid condition having then existed for a little over two years, the only sign presenting encouragement lay in the biceps for transplantation, together with fixation of the ankle joint, but this chance seemed remote. The mother, however, desired any steps taken which might offer the slightest prospect of betterment, rather than to have the child helpless for life, and unable to earn his living, and operation was decided upon. This was performed June 5th last. The technic pursued consisted of the transplantation of the biceps tendon into the patella, and a double fixation at the ankle joint. With the foot in the corrected position at right angles to the leg, one screw was passed through the external malleolus, astragalus, and calcaneus, another through the internal malleolus almost at right angles to the first, while a third screw was passed through the scaphoid and cuboid, fixing the key of the arch of the foot. The head of the femur was returned to the acetabulum and a plaster of Paris cast snugly applied from the foot to the costal margins, and allowed to remain on for six weeks. The wounds healed by first intention. Passive motion and massage were then instituted, and the weight of the body gradually applied to the foot, now firmly fixed at the ankle joint. Minute instructions were given to the mother as to the training of the child to walk, and as an aid to this end a simple device of the footbridge effect, with hand rails was built out of doors close beside the house for daily exercise. The child held to the rails while his feet were in the beginning picked up, and carried forward in the earliest attempts to walk. Two perfectly straight strings were laid upon the ground between the rails, upon which the child’s feet were placed, so that he might be taught, as far as possible, to walk straight from the beginning, and intended primarily to aid in overcoming the external rotation of the thigh, eversion, and abducted foot effect. The power of the biceps soon manifested itself, changing its action from flexion to a very slight extension of the leg. The foot held firmly in the right angled position.

Fig. 1.—Showing apparently flaccid paralysis and pointed toe of affected limb. Note difference in size and position of the two limbs. (Taken just before operation.)
Improvement at first was very slow, and at times very discouraging, but progress has continued steadily and without retrogression to date. The gain in strength to the leg, the increase in size of practically all the muscles, the marked growth of the child and the improvement of his mental and physical condition have been most gratifying. He could walk short distances, fifty or sixty feet, without any assistance whatever. He could stand the weight of his body upon the affected leg without its buckling beneath him. He enjoyed his exercise in the open air and sunshine on his little foot path with rails, and was quite delighted with the idea that he had been taught to believe, viz., that he would soon be able to walk and play like other little boys. The external rotation of the thigh, with its eversion and abduction effect upon the leg and foot, still persisted, but I had as yet made no attempt to correct this, further than by the use of a little adhesive plaster running from the thigh above the knee on one side across to that of the other, which served very well indeed for a temporary correction of the deformity. It gave him the wider pedestal upon which to walk and stand. This was deliberate in the earlier stages of the treatment I believe that "suits of armour bristling with screws and ratchets, where it is possible to do without them, are a decided disadvantage. They are an absolute hindrance to the freedom of growth and development and the early acquisition of strength to the affected limb, and of all considerations these are paramount. Once safely secured, resort to mechanical devices is in order. Up to the present time, the first plaster cast excepted, no splints whatever have been utilized.

TENDON TRANSPLANTATION.

It is undoubtedly true that a muscle that is stretched over a long period of time ceases to act, likewise that if the strain on an overstretched muscle is relieved its power of contraction is regained. The muscle whose function is lost because of overstretching is one thing; the muscle that is paralyzed because of the destruction of its motor cells is another. Functional restoration of an over extended muscle is more common by posture than by the action of a transplanted tendon. Reactions of degeneration are quite untrustworthy, especially.

"Since this paper was written the patient's progress has been very satisfactory. He can now walk fifty yards without the slightest aid.

in the earlier stages of paralysis. Hoffa and Lange, Koch and König, have all shown that muscles recover by posture after the reactions of degeneration have pronounced them hopeless. Koch's histological studies led to the conviction that even in useless muscles it is possible to regenerate muscle fibre, and he quotes instances of muscles microscopically showing complete degeneration which later recovered.

The double purpose of tendon transplantation is, of course, to correct deformity and to restore function. Properly done, total failure is rare. This justifies the operation. Its indications are as follows: To strengthen a weak muscle or group; to replace a paralyzed muscle or group. Essentials to success are: Adequate preliminary correction of the deformity; prevention of adhesions of the tendon; amble freeing of the tendon; prevention of angular deflection of the tendon; adequate tension of the reinforcing muscle; absence of overstrain upon the transplant; the sheath should be preserved intact and accompany the tendon, since its blood supply is from the sheath as well as from its bone insertion; accurate and smooth suture fixation of tendon; massage, passive and active motion of the tendon, free from body weight, should always precede the heavier strain of body weight; power when once manifest, should be continually increased, otherwise somebody is to blame, the surgeon or the patient. The vitality of a muscle may be judged by its appearance: If healthy it is dark and red; otherwise, it is pale pink, or fatty, in color. It may be necessary to remove skin flaps to secure
an over correction; tunneling should be done in one plane; careful, patient, painstaking nursing of the tendon and education of the patient are most valuable; likewise, a bloodless field of operation through the tourniquet; and a faultless aseptic technic as a matter of course.

POSSIBILITIES OF CURE.

The operation to be successful must be followed by long and careful aftertreatment, anticipating the sequence of events. Any lack of faith on the part of the surgeon is only too soon transmitted to patient and friends and hope is early abandoned. Rest is a tremendous factor in restoring power to overstretched muscle power, and postural prophylaxis is of immense importance. In paralytic deformities the chief factors are: Gravity, body weight, inequality of muscular action. Recognition of this unbalanced muscular action is the keynote to treatment, both operative and mechanical. The great error has been to assume that certain groups of muscles irresponsible to stimulation are lifeless and that there is cell destruction in the motor area. To the contrary, actual cell destruction is nothing like so common as one might suppose, the condition often being transient and recoverable. Until this fact is accepted, the potentialities for recovery are not realized.

Splicing should be as smooth and neat as possible. Clumsy projections cause adhesions and prevent the easy motion of the tendon. Opponents of contracted muscles are always elongated. A reinforcing tendon should be fixed in the paralyzed tendon with the latter taut. A slackened tendon will not do its work. It is of great importance in the first attempt at walking to see that the body weight is correctly poised upon the tarsus. Exercises should be made as interesting as possible to the child. Motions opposed to the direction of the deformity should be given preference always. A movement that gives the greatest difficulty is the one deserving of the most frequent practice. All movements at first should be executed with care and deliberation. With deformities even partially corrected, the mental and physical condition of the patient improves wonderfully as a result of his mixing with other children. Recovery is always slow because of the successive steps necessary in each case—first, operative; second, mechanical; third, educational. The patient must be under the absolute control of the surgeon for at least twelve months, often for two years. If this is denied, the attempt had better not be made, for operation without careful and prolonged aftertreatment can only result in discredit to the surgeon and disappointment to all concerned. Pitfalls are many. Superincumbent body weight too early applied to a tendon transplant may be fatal to an otherwise slow but successful function. An extensive muscle group affection may not involve a correspondingly large paralysis of the nerve centre, for opposing muscles, the weight of bed clothes, or the force of gravity may continue a deformity without the presence of a paralysis. The overcorrected position must be maintained sufficiently long to permit the overstretched muscles to take up the slack—to shorten.

CONCLUSIONS.

The writer is of the opinion that many cases of infantile paralysis, regarded as hopeless, are ame-
nable to the treatment herewith suggested. The double fixation method with tendon transplantation in paralysis of the lower extremity is, he believes, a valuable surgical asset. It is an effective substitute for arthrodesis, much less destructive of tissue, quicker in result, much surer and much simpler. Further, it does not permanently destroy the integrity of the joint or entail the extensive destruction of bone, or cartilage, or both, and does not have to wait for the dictum of the “tenth year” in order to be effective. Again, these screws can be removed when strength to stand and muscular function are firmly established, thus restoring at least in part the integrity of the ankle joint. At this late date of removal recurrence is quite improbable. We may style the scaphoid and cuboid bones the key to the arch of the foot, and their fixation at this critical period with that of the ankle joint itself adds material strength to both. It is very effective in the prevention of toe drop. That the screws may act as foreign bodies is an exaggerated fear. Foreign bodies become active only in the presence of infection. Lexer and Lane have shown this conclusively.

A double fixation is a double strengthening. It makes assurance doubly sure. The footbridge with handle bars and strings upon the ground running parallel is, I am persuaded, an effective device, the simplicity of which is its recommendation. The value of the open air and sunshine, in connection with the exercises as carried out with this device, is patent. The little patient early learns to become independent of another’s assistance, which stimulates and encourages self confidence. Properly directed nothing else is quite comparable to the patient himself exercising his own muscles. Self reliance has no substitute.

The Farragut.

**REVIEW OF CONCLUSIONS DRAWN FROM THE FREUDIAN SCHOOL.**

**By Meyer Solomon, M. D.,**

Assistant Attending Neurologist, Maimonides Hospital.

All thoughts, all passions, all delights, Whatever stirs this mortal frame, Are but the ministers of Love, And feed his sacred flame.

—Coleridge.

If “love,” as employed by Coleridge, means “sexual love,” then, it seems to me, Coleridge has expressed, poetically, the essence of Freudian contention and the tendencies and intimations of the Freudian school.

The tendency toward psychoanalytical work by the Freudian school cannot be too highly praised. The dynamic viewpoint and many of the mental mechanisms employed by the Freudian school have done much to give us a new feeling, living, thinking, human psychology. Freud and his disciples have given us an impulse and inspiration for psychoanalysis. But where the Freudian school makes its great mistake is in making each psychoanalysis a sexual analysis. Psychology and sexology are not synonymous. Psychoanalysis should not mean sexual analysis alone.

The writer is opposed to many of the sexual ideas of the Freudians, not because he believes the subject of sexuality to be unclean and unworthy of investigation, but because he is certain that the Freudians are seriously in error in many of their ideas. Their sexual theories may apply to some cases, or may have a contributory relation in many instances, but they are not deserving of all of the importance which the Freudians assign to them.

I will not endeavor here to enter into a critical review of Freudism. I wish merely to call attention to certain conclusions which must logically follow, if certain declarations of members of the Freudian school are true. To bring home my argument most forcibly I need but enumerate some of the extensions and generalizations to which one is inevitably led if he believes in these false ideas.

This brief enumeration will, I am certain, suffice to show how extravagant and rash many of the Freudians have been in their dogmatic assertions. It is because so many of their ideas are untrue, and hence most pernicious, that Freudism, as it stands to-day, must in the end fall into disrepute and slowly but surely crumble into dust and be no more. The stimulus which the Freudians have given all of us for psychological analysis will lead to a firmer, truer, more lasting, more stable, and more scientific psychology.

I shall confine my remarks to the question of sexuality. And let it be at once understood that I use
the term sexual in the broadest possible sense; at least in as broad a sense as Freudians themselves. this including possible incestuous, bisexual, and polymorphous perverses sexual tendencies, physical or psychic.

Let us begin with dreams. Freudians believe that dreams practically always have a sexual meaning. Even if they limited this generalization to the dreams of neurotics, it would have a universal applicability, since the difference between a normal and a neurotic individual is one of degree only. Consequently, if the dreams of neurotics are fundamentally based on sexuality, then all the dreams that any of us have are dependent on sexuality. Now, the difference between the sleeping state, the waking state, and other states of consciousness is essentially quantitative. It therefore follows that the trend and content of the mental processes of every possible mental state is centered about sexuality. In other words, not a thought we have but what is ultimately dependent on sexuality for its origin. This, as will be appreciated later on, is practically what the Freudians really tell us in an indirect and circuitous fashion.

If, as Jones\(^1\) positively asserts, morbid anxiety means unsatisfied love (and Jones uses "love" in a purely sexual sense), since the difference between common, ordinary, everyday anxiety and so-called morbid anxiety is absolutely one of degree alone, then one must conclude that every possible state of anxiety or expectation, however slight in degree or brief in duration, springs in like manner from sexuality.

Again, let us consider what Jones\(^2\) tells us about the underlying therapeutic action of suggestion. He states that in all methods of mental treatment, except in psychoanalysis, affective suggestion is the principal cause of the beneficent results. Under this he would include treatment by persuasion, reeducation, hypnotism, suggestion, simple encouragement, electrotherapy, gymnastics, massage, Weir Mitchell treatment, etc. So far, so good. But Jones goes further and says that the methods by which suggestion acts in therapeutics is as follows: "The repressed sexual affects are withdrawn from their previous expression in various symptoms, and become attached to a more suitable object, namely the person of the physician." This, to me, means but one thing. All dependence is sexual. I am prompted to ask: Is all authority sexual? Do we value or worship nothing for other than its sexual significance? Does man sexualize the universe?

Let us go one step further. I think you will agree with me that hypnotic states, hypnotical states, daydreaming, the mental condition of a patient who is giving free associations, etc., are all gradation steps differing in degree of consciousness. What is a fixed law for any one of them applies just as rigorously to all the rest. If, then, sexuality is the mainspring of hypnosis, it is the fountain head from which all these other mental states also spring.

Moreover, if sexuality is at the basis of hypnosis, it must be at the basis of all suggestion, and, likewise, of all negativism. To put it more plainly, if

Jones's contention be true, then all agreeable and disagreeable human relationships must find their raison d'être in sexuality.

Freudians tell us that neuroses are the negative of sexual perversions. In other words, if Freud's dictum be true, then all neuroses, as the Freudian school indeed asserts, are the outgrowth of sexuality. It must be generally acknowledged that the real difference between neurotics and the rest of us is one of degree—of degree in physiological stability of the nervous system, of degree in adaptability, of degree in resistance to shock, to stress, and to strain, of degree in self control, and in nervous equilibrium. Consequently, what is an absolute law for neuroses must be directly applicable to all other mental states. If neuroses are the negative of sexual perversions, then all other psychic states are the negative of sexual perversions.

If, as Freud and his school have agreed, hysteria is based primarily on sexuality alone, then every possible dissociated state (such as states of distraction, dementia praecox, etc.) is dependent on sexuality.

If the somatic symptoms of hysteria, said by Freudians to be due to "conversion," take their origin from sexuality, then all unconscious and automatic activities must depend on sexuality.

If the root of alcoholism is to be traced to sexuality (homosexuality), as Freudians declare, then all drug and drinking habits must be dependent on sexuality. And if all so-called narcomaniacs are conditioned by sexuality, then, since the desire for strong drinks and drugs differs from normal drinking and eating in degree alone, all nourishment, all gastrointestinal activities and yearnings, whether in neurotic or normal individuals, must, in like manner, be fed from the stream of sexuality. If this be true of gastrointestinal conditions, must we not then agree that sexuality is the alpha and omega of all habits? And, further, since our habits are but the prolongation of our instincts, if all habits derive their origin from sexuality, then all of our instincts have so arisen. In other words, if Freudian conclusions be true, all of our instinctive energy is sexual. (See later on for comparison of vital energy with libido.)

An effort is being made to prove that all psychogenic epilepsies take their source of origin from sexuality. If this is believed, functional tremors, spasms, etc., come within the purview of the same generalization.

Is thumbsucking always a sexual manifestation? Is true bronchial asthma a sexual symptom? Is bedwetting, when not due to epilepsy, always of sexual significance? Certain Freudians practically tell us so, sometimes frankly, at other times by innuendo. Are not these conditions indications of an unstable nervous system or the result of excitement by strong stimuli along paths nervously connected? Is all bodily yearning, all bodily gratification, all feeling of satisfaction of sexual makeup?

Many Freudians tell us that paranoia (which term includes paranoid and paranoid states) is the offspring of homosexuality. Suppose this were true. What would it mean? It would mean that every idea of persecution, of crowding, of suspicion, of dislike, etc., whether ill or well founded,

\(^1\)The Pathology of Morbid Anxiety, Journal of Abnormal Psychology, June-July, 1911.
must find its seed planted in the fertile field of sexuality. Moreover, if, as Freudians will have it, the exaggerated ego of paranoia finds its birthplace in so-called sexual narcissism or self love, then all feelings of satisfaction, of self congratulation, of pride, etc., and their opposites are the outgrowth of sexuality. To present the dictum in a forcible way, we may say that Freudians must believe that all psychic attraction and repulsion, all mental processes, flow from the well of sexuality.

Suppose, for the sake of argument, that sexuality is always the substratum of hysteria. The logical conclusion follows that sexuality is the cornerstone of dementia precox. And if dementia precox must kneel at the footstool of sexuality, are we not next compelled to assert that all psychoses, and hence all mental states, have a sexual foundation?

Is all mental normality and aberration (abnormality) centred about sexuality? Cannot these conditions find their causation in the development or disturbance of any of our other instincts?

Is all sublimation sexual? Don't we ever sublimate from any of our other instincts?

Do Freudians mean to tell us, as indeed they intimate and openly say, to judge from their ideas concerning the method of action of suggestion, and the stress they lay upon the incestuous, bisexual, and polymorphous perverse sexual tendencies they see so glaringly present in infantile activities, in dreams, in the neuroses, etc.—do they mean to say that all gregarious, social, and familial tendencies, all human relations between members of the same or opposite sexes are fundamentally sexual?

Freud and his school limit the term neurasthenia to a condition which is the result of certain physical sexual causes, and they call this "true neurasthenia." Why is neurasthenia of sexual origin any truer neurasthenia than neurasthenia from other causes? Surely Freudians do not mean to tell us that the neurasthenic syndrome which is characterized by "an inordinate sense of mental and physical fatigue, 'brain fog,' and difficulty in concentration of attention and application to work, sense of pressure on the head, irritable spine, and various paresis, particularly of the joints and muscles," is always of sexual etiology. If this is their viewpoint, then they must believe that this group of symptoms, when occurring as a primary condition, cannot possibly be due to any other disturbance than that occurring in the sexual sphere, and when due to any other cause it must be called secondary or neurasthenoid.

If we would follow the Freudians, we must believe that the very flow of life and the energy which pervades the universe is sexual. That, in fact, is just what Jones tells us when he states that "it will be seen that the importance he (Freud) attaches to the (sexual) instinct does not greatly differ from that of Schopenhauer's and Nietzsche's 'Wille zur Macht,' Bergson's 'élan vital,' Shaw's 'life force' and the 'vital impulse' of so many writers, all of which are equivalent to what Freud terms the 'libido.' He replaces these metaphysical and poetical phrases by a scientific and biological one—one that is also in harmony with the sound intention of the people manifested, among other ways, through language, an example being the etymological unity of the words 'love' and 'life.'" Jung employs the term "libido" as being synonymous with vital impulse but broadens the meaning to apply not only to the sexual impulse but to all manifestations of vital energy, such as nutrition.

Libido smacks of sexuality. And to most Freudians as well as to the rest of us, libido means sexual impulse. Moreover, the term libido is no more explanatory than any of the other terms employed. Without using the term libido, Low tells us in beautiful and powerful language of that all pervading upward struggle for self expression. To him

"Every cloud feels a stir of might.
And groaning blindly above it for light
Climbs to a soul in grass and flowers."

I maintain that the word libido cannot be substituted for the term vital impulse, that the sex instinct is not the only instinct possessed by man, and what is biologically significant—and there is nothing in the universe which is not—is by no manner of means necessarily of sexual significance.

All life is not sexual. All love is not sexual. We may love things for their value in self preservation, for their appeal to any of our instincts.

Of course Freudians may contend that the search for happiness and self expression is significant of love of self, and, being a low grade of narcissism, is thus sexual. But we know that these tendencies are manifold and of all other forms of life, though frequently under conscious, intelligent direction, are, however, essentially unconscious and instinctive. Is this instinctive, biological tendency also sexual or libidinous? Freudians evidently think so. Their best efforts are being expended with the object of proving all unconscious activity to be of a sexual nature. Does not Jones definitely declare that the vital impulse and libido are one and the same thing?

There is one standpoint from which the universe could be viewed from a sexual basis. Briefly stated this viewpoint is as follows: From the biological standpoint every atom and every spark of energy in the universe may be of some significance—advantageously, disadvantageously, or indifferent— to every human being. Biologically considered everything may have some possible relation to our self preservation or self expression. All phenomena are useful, harmful, or indifferent, intimately or most remotely, to every one of us. And since man, though originally bisexual, is of one or the other sex, all possible phenomena throughout the universe, being of some significance to him biologically, even though as a rule he be unaware of it, are consequently of sexual importance. But why take man as the centre of the universe? In the broad scheme of nature man is of no more importance than are all the animals below him, than the air above him, the water and earth beneath him, the grass and trees about him, and the stars and planets beyond him. Looked at from the standpoint of such inanimate and sexless objects as water, air, stone, or what not, all phenomena and all things can be shown to have some possible relation to any of

---

2 Jung: Wandlungen und Symbole der Libido.
them. The former viewpoint, therefore, is indefensible and false. And yet, this, practically, seems to be the manner in which some Freidians contemplate the situation. Their explanation of the exaggerated ego in paranoia (as being based on sexuality) tells the tale.

Do love and life mean only sexual love and sexual life? Is all unconscious thinking sexual? Are all unconscious processes sexual in nature? Is all intrapsychic struggles sexual? Is sexuality the underlying impulse in physiological tropisms, in physicochemical reactions, in all attraction and repulsion, physical or psychic, in the organic or inorganic world?

The Freudians have assumed a purely psychological viewpoint. They have confined their psychology to sexology.

The biological viewpoint is the basic method of approach to a study of the mind of man. Biological relations cannot be explained from a purely psychological conception of the universe. And psychological relations can be explained not from the psychological aspect alone, nor even from the biological standpoint alone, but only on a psychological basis.

Man can be understood only if we agree that he is composed of a bundle of instinctive tendencies. Man does not breathe and eat and digest and sleep and dream and exercise his physical and psychological faculties because he is constantly demanding and seeking gratification of his complex sexual impulse, no matter how broadly this term be construed, but because he instinctively, innately, and frequently blindly, must strive and tend toward self expression all his livelong life.

In conclusion I wish to state that these questions have not been propounded with a feeling of fixed antagonism and blind hostility, but with a sincere desire to know "the truth, the whole truth, and nothing but the truth."

If certain Freudian teachings regarding the role of sexuality are not according to facts as we know them to be, then they should be quickly and surely bombarded and shattered. And the sooner this is done, the better will it be for science and for psychotherapy.

BLOOD PTOSIS.
A Test of Vasomotor Efficiency.*

By C. Ward Crampton M. D., New York.
Director of Physical Training, Department of Education.

We have few if any accurate scientific tests of health. On this account school hygiene shares with other branches of medicine a difficulty in quickly and certainly testing the failure or success of its methods. We labor to improve the health of school children and to increase their prospects of life by physical training, athletics, instruction in hygiene, school lunches, open air classes, changes in ventilation and the like and invariably experience difficulty in clearly and honestly stating what gain

has been made by our work. It is true that such records of rates of increase and decrease of hemoglobin have their value, and certain strength and endurance tests have some merit, but they are all subject to error, and are incomplete or difficult to control.

During the course of an exhaustive study on blood pressure I presented a preliminary report on a test which fulfills the latter requirements.2

It is a statement of the efficiency of the vasomotor system in responding to the necessity of raising the blood pressure upon rising from the recumbent to the standing position.

In the perfectly normal vigorous male the blood pressure will rise from eight to ten millimetres of mercury upon assuming the standing position. In one damaged by disease, overwork or unhygienic living or weakened by inactivity, the blood pressure will fail to rise and may fall as much as ten millimetres of mercury. The heart rate acts in exactly the opposite fashion, rising in proportion to weakness as much as forty-five beats a minute, but only in exceptional cases falling. These two adjustments are interdependent, one often masking the failure of the other, and both must be considered and balanced. If blood pressure were alone considered many cases showing a high heart rate would be given a good rating when it should be poor, and vice versa. This test has been put into regular routine practice by R. Tait Mackenzie, M. D., of the University of Pennsylvania; George H. Meylan, M. D., of Columbia University; Doctor Raycroft of Princeton; Doctor Storey, of the College of the City of New York; Doctor Marks, of Pittsburgh: Doctor McCurdy, of Springfield, and others in examination of athletes for "permission to compete" and for other purposes. It is based upon the following facts:

If the blood were contained in flaccid tubes without support it would, upon standing, drop to the lowest possible point and remain there. There would be none to reach the heart and none would be pumped to the head. A complete blood ptosis would occur and death would result at once. This does not occur because there is some mechanical support and the blood vessels are not flaccid but held to a narrow lumen by circular muscles, in turn controlled by the sympathetic nervous system. The most capacious system of blood vessels in the body are the splanchnic veins; these can hold all the blood volume if released from the vasoconstrictor efforts of the nervous system.

In the perfectly normal there occurs upon rising from the recumbent position a vasoconstriction effort which squeezes these veins and raises blood pressure which more than overcomes the added hydrostatic load. In the subnormal this vasoconstriction effort is relatively weak and ineffective and does not raise the blood pressure in the upper body, but allows it to fall under hydrostatic pressure. There is a blood ptosis due to the relative failure of vasomotor tone. This may be mild, merely a failure to raise the pressure or a fall of the systolic pressure five or ten millimetres, in which case we

*Abstract of address at the Fourth International Congress on School Hygiene, Buffalo, August 28-30, 1913.

2Physical Education Review, 1913-1915; Medical News, September 16, 1905.
November 8, 1913.

CRAMPTON: BLOOD PYOSIS.

917

may still call our patient fairly normal. It may be a more complete failure, allowing the systolic pressure to drop to forty or fifty, at which point the patient faints from cerebral anemia. This is the familiar picture seen when a convalescent patient with vasotone damaged rises prematurely from a sick bed, and, robbing the splanchnic veins of mechanical support by emptying the bladder, falls to the floor.

The most severe grade of vasotone paralysis occurs as a terminal phenomenon in poisoning from disease in which case the patient literally bleeds into his abdominal veins and dies. Vasotone is then a function essential to life; a delicate measurement of its efficiency such as is indicated in the foregoing is worthy of consideration as an important indication of the condition and vitality of the whole body, which depends upon vasotone for its proper functioning.

It would then seem to be necessary merely to observe the amount of rise or fall of the systolic pressure at a convenient point in the upper body to determine the efficiency of the vasomotor system and its reverse, the amount of blood piosis.

Another fact presents itself in the increase in heart rate which accompanies vasotone failure. Hill states that the heart, as it were, comes to the rescue of the falling pressure by beating faster in a successful endeavor to reestablish it, its rate increasing in proportion to the necessity. In this case we would discover weakened vasotone by either increased heart rate, or fall in blood pressure, or both, but only by taking both into consideration, we may arrive at a correct estimation of the weakness. Another explanation maintains that the increased heart rate does not raise the pressure but merely reveals it, for the heart furnished with a lessened charge of blood is able to send it into the arteries more quickly.

From my own observation it is clear that a single patient will show in successive readings a variation of blood pressure and heart rate which compensate each other, while the consideration of both will reveal no change in vasotone efficiency.

The balancing of these two is a matter of some importance. The usual range of the systolic pressure is from +10 to -10 of the heart rate increase from 0 to 44, as observed from records of a large number of cases. Upon a statistical balancing of these two series of frequencies, and assigning equal percentages to equal ranges, the following scale is constructed.

PERCENTAGE SCALE.
Vasomotor Tone.

<table>
<thead>
<tr>
<th>Blood Pressure: Increase</th>
<th>Heart rate: Increase</th>
</tr>
</thead>
<tbody>
<tr>
<td>+10</td>
<td>+10</td>
</tr>
<tr>
<td>+8</td>
<td>+6</td>
</tr>
<tr>
<td>+4</td>
<td>+2</td>
</tr>
<tr>
<td>0</td>
<td>-4</td>
</tr>
<tr>
<td>-6</td>
<td>-8</td>
</tr>
<tr>
<td>-10</td>
<td>-10</td>
</tr>
</tbody>
</table>

This scale provides a convenient and intelligible method of recording and reporting cases and permits a numerical statement of the function in question. Its 100 mark indicates a perfectly efficient working of the vasomotor system under test, the zero is approximately the point where the average person is unable to maintain the erect posture.

The technique of the test is as follows:

The sphygmomanometer is adjusted over the brachial artery and the patient is placed on a comfortable couch with a low pillow. The heart state is counted by quarter minutes and a gradually decreasing rate is usually observed. Counting should continue until two successive quarter minutes are the same, this is multiplied by four and recorded. The systolic pressure is then taken preferably by auscultation. The patient stands, the heart rate is counted as before until it reaches the "standing normal," when it is recorded, and the blood pressure is then taken. The differences are calculated and reference is made to the scale.

For example—Case XX: L. V., age seventeen years, asserts to be in good condition at 11:20 a.m.

<table>

<tr>
<td>Percentage</td>
<td>20</td>
</tr>
</tbody>
</table>

This is a very poor record taken from an apparently normal strong young football player of exceptional ability who had previously given records above 80.

I was at a loss to account for this, for questioning failing to bring out any history of loss of sleep, dissipation, or illness. He looked quite as "fit" as usual. He was absent next day, and remained home for a week with a "cold and fever." It is evident that the test revealed a weakened vasotone, the beginning of actual illness before any other symptom could be noted. Others who have used this test have noted similar cases.

This test has been used to follow athletes through a course of training and as the basis for choice for the entry of one of several athletes of equal ability in an important race where only one might compete. It has been used to guide the daily exercise of athletes to guard against overwork and approaching staleness. It has been found useful in guiding treatment of the neurasthenic and overworked.

It has been used in school hygiene to determine the amount of physical cost of school procedures of various kinds. The following is a typical record.

<table>
<thead>
<tr>
<th>Time</th>
<th>Increase pulse rate</th>
<th>Increase blood pressure</th>
<th>Percentage</th>
<th>Remarks</th>
</tr>
</thead>
<tbody>
<tr>
<td>9:45 a.m.</td>
<td>0</td>
<td>+10</td>
<td>100</td>
<td>Slept well, no exercise.</td>
</tr>
<tr>
<td>10:45 a.m.</td>
<td>0</td>
<td>+4</td>
<td>85</td>
<td>After lesson in physics standing.</td>
</tr>
<tr>
<td>11:50 a.m.</td>
<td>+8</td>
<td>+10</td>
<td>95</td>

<td>After history lesson.</td>
</tr>
<tr>
<td>2:35 p.m.</td>
<td>+16</td>
<td>+4</td>
<td>70</td>
<td>After slow mile run.</td>
</tr>
</tbody>
</table>

This shows that one period of work in the physics laboratory (which required continued standing) was more expensive than a slow mile run. It also showed that this was partially regained in the next period, lost again during the
French period, and partially regained by rest at the lunch period. This record also shows the importance of considering both heart rate and blood pressure.

This test opens a wide field of investigation hitherto unworked. The effect of various modes of ventilation, of feeding, exercise, and other hygienic procedure may be tested and recorded in terms which may be statistically stated and easily compared with a control series of records.

It has been used to test the amount of relaxation of vas tone resulting from various forms of physical exercise, and shows clearly that exercise is expensive of nervous energy and should be followed by rest and recuperation.

This test will not reveal more than it assumes to test, i.e., the efficiency of the vasomotor system. It will not show the presence of a mitral lesion any more than it will a decayed tooth. Nor will it test other factors of efficiency such as will power, inhibition, or skill: it does provide a means of making a definite record of an all important bodily function. Those who work to mould schoolroom and other living conditions for the purpose of improving health and efficiency may be able by this means to measure the benefit resulting from their labors.

431 Riverside Drive.

THE REFLEX OR PROTECTIVE PHENOMENA OF ANGINA PECTORIS.

By W. J. Pulley, M. D.,
New York.

It is not my purpose to-night to discuss angina pectoris in detail, but to confine my remarks to a discussion of what James Mackenzie calls the reflex or protective phenomena of it. I have chosen this part of the clinical picture of angina pectoris to talk about because it seems to me to be more or less definite and explainable, while the causative pathology, symptomatology, etc., are more or less indefinite and variable, and furthermore, there are two additional points about it which I consider important and which I have not seen sufficiently emphasized in the literature of the subject. For fear of becoming too dialectic I will state simply that the heart, according to Engelmann and his followers, has five functions more or less well defined, viz.:

1. Stimulus production or rhythmicity. The heart takes a certain length of time to produce enough stimulus to cause a normal contraction, and the length is the same between all of the beats.

2. Excitability, or the power of being able to receive stimulus.

3. Conductivity, or the power of conveying stimulus from fibre to fibre.

4. Contractility, or the power of contracting when stimulated.

5. Tonicity, or the power to retain a certain amount of contractility between the active movements.

There are some who deny that these heart functions can be isolated and definitely demonstrated, and the principle reasons they point out as against it is that, taking the assumption as a basis, many of the cardiac irregularities cannot be explained.

However, since Mackenzie has perfected the polygraph and Eithoven the electrocardiograph, a rearrangement of any of the known functions of the heart can be demonstrated. Exactness of results acquired from the use of these instruments was made possible by animal experimentation.

James Mackenzie says: "I have a great many tracings from patients who have suffered from angina pectoris—during the attacks and when free from pain—and an analysis of these tracings enables me to say with confidence that angina pectoris can occur when the excitability, the conductivity, and the power to produce rhythmic stimuli are unimpaired. There only remains now the function of tonicity and contractility. The evidence of failure of the function of tonicity is mainly shown in dilatation of the heart, and typical attacks of angina pectoris frequently occur in hearts perfectly normal in size. Therefore angina pectoris may occur without any evidence of the impairment of the function of tonicity. Seeing that angina pectoris can occur in patients when four out of five functions of the heart muscle are demonstrably intact, we are led to inquire whether angina pectoris may not be due to an impairment of the remaining function, that is contractility."

Carrying out this line of reasoning, he states that it is his opinion that angina pectoris is an evidence of an exhaustion of the function of contractility. To my mind this looks to a great extent reasonable, at least it gives us a very attractive way of explaining some of the symptoms of angina pectoris satisfactorily, especially the reflex ones, only two of which we will deal with in this paper. Pain and reflex muscular contraction are the symptoms here referred to, both of which are reflexly produced and protective in their action. That these reflex phenomena are due solely to an impairment of the contractile function of the heart does not, I believe, explain the entire situation, for there must of necessity be present with it a great distress of the function of tonicity, if not a beginning impairment. Mackenzie uses the words exhausted and impaired here, evidently leading one to infer that the power of the heart muscle to contract is partly, at least, lost. I think the real condition of affairs would be more correctly stated by saying that the heart muscle is embarrassed and fatigued by contracting against an abnormal obstruction modified by certain conditions, for the heart muscle must be to a great degree intact in order to send out the stimuli so constantly and strongly as to produce irritation in the reflex nerve centres.

In a heart muscle in which the function of tonicity is impaired these symptoms of angina pectoris do not usually occur, even if the function of contractility is embarrassed. In order then to have these reflex phenomena occur, clearly there must be an overstimulation of the function of tonicity as well as of the function of contractility. As a proof of this I will cite you a case taken from my files, in which repeated attacks of angina pectoris occurred, until the function of tonicity became impaired, a after which they became greatly modified and finally ceased altogether. The impairment of the function of tonicity was easily recognized by the development of a systolic murmur at the apex, evidently a relative mitral insufficiency and a slight
displacement of the cardiac apex downward and to the left. From that time on, which is six years now, the patient has been practically free from the intense pains in his chest. In the beginning of this patient’s trouble, walking one block, if it was up hill, or the slightest indiscretion in eating, would bring on an attack. Proper dieting, with physical and mental rest and high colonic irrigations, produced the good results obtained in this case.

The mechanism by which pain and muscular contraction in angina pectoris are produced is described in the first instance as a viscerosensory reflex, and in the second as a visceromotor reflex mechanism. Sherrington, Langly, Gaskell, and Mackenzie have worked this out very elaborately.

The heart, like all of the internal viscera, is insensitive to ordinary stimuli. Physiologists and others (Howell, Gaskell, Mackenzie) teach us that the internal viscera are not supplied by the ordinary somatic nerves of sensation and motion, but get their nerve supply from the autonomic or sympathetic nerve system, and that these viscera can be handled, pinched, and bruised without giving any pain, but on the other hand force any of them, especially the hollow muscular ones, to be overworked or contracted against an obstruction, and we immediately have symptoms of pain, referred not always over the site of the viscus involved, but in a great number of instances to some other part of the body. These are the so called referred pains described by Head, Mackenzie, and others.

Embryologically, all of the hollow muscular viscera, as the heart, bloodvessels, digestive tubes, uterus, ureters, etc., have a common origin, but specialization causes them to take different functions later on. Examples of the referred pains here spoken of may be noted where calculi obstruct the ureter and some of the pain at least is referred to the testicle, also pains in the right shoulder in gallstones, pain in the epigastric region in appendicitis, due really to pyloric spasm. In case of the heart, experimental physiologists have proved that its muscle walls are supplied or enervated by the vagus, which gives to it its inhibitory fibres, and by the sympathetic, which supplies it with accelerator fibres passing to the heart, and depressor fibres passing from the heart. However, the matter is not concluded here, as Mackenzie states, for the personal sensation of the animal cannot be communicated to the experimenter. There is unquestionable evidence in dealing with symptoms of heart affections that there is, in addition, a system of nerves not yet definitely described, passing from the heart to the lower cervical and upper dorsal segments of the cord and to the bulb, and that these afferent nerve fibres carry stimuli from the heart to the nerve centres and there, by a summation of stimuli, or by a very violent and sudden stimulation act as irritants, which in turn affects the nearby origins of the sensory and motor nerves, with the resulting symptoms of pain and muscular contraction, referred to the part of the body to which these last named nerves are distributed.

When the heart muscle, for instance, contracts for any length of time against an obstruction of long standing, or against a sudden violent obstruction, as in severe physical exertion, there must of necessity be an increased amount of stimulation produced to cause such contractions, and this is passed out from the heart over the efferent nerves so constantly and with such force to the centres in the cord and bulb that exaggerated irritation is produced. This irritation affects the nearby nerve origins and then ensues pain in the chest, of a squeezing viselike character, due to contraction of the intercostal muscles, and pain in the neck, radiating along the inner side of the left arm, due to nerve irritation.

The pain in the chest varies from an oppressed feeling to a viselike excruciating pain, which latter causes the patient to sit rigid and breathe superficially, and to be possessed of fear that death is imminent. This is the classical type, but there is another more or less common type, referred to often as pseudo angina pectoris, in which the pain is of a more aching character, the patient’s face is flushed, and there is a constant changing of position to be rid of the pain. To call this pseudo angina pectoris is incorrect, for it is just as true an angina pectoris as that of the classical picture, the difference being the arterial change is less far advanced in one case than in the other. Not every patient, but a large majority, suffering from angina pectoris, have vascular supertension, and it is this continuous obstruction to the heart contractions which ultimately embarrasses the contractile function of the heart. The pains are protective, in that they cause the patient to cease most muscular efforts, which tends to rest the heart by taking just that much extra work off it and gives it a chance to regain some of its lost reserve. The fear produced in the patient by these attacks also has a protective tendency, in that it causes the patient temporarily to cease worries of all kinds and excesses of all kinds, thereby tending to lower vascular supertension and rest the heart. The flushed face, in the other class of cases, is due to reflex stimulation of the vasodilators of the superficial capillaries, which also tends to reduce vascular supertension. The contraction of the intercostal muscles is protective, in that it tends to prevent deep breathing, and tends to act as a splint to protect the already stretched and weakened walls of the aorta. Deep inspirations tend to increase the arterial tension (De Jaeger, Howell). Another instance of the protective action of muscular contraction in angina pectoris occurs where the patient suffers from so called cardiac asthma. This is really a resistance on the part of the circular muscular fibres of the bronchial tubes to a deep inspiration and consequently an increase of arterial tension. The vagus supplies the circular muscular fibres of the bronchial tubes, and this reflex contraction probably comes through it, because its origin is near the respiratory centre in the medulla. The musical rales heard in cardiac asthma are alike in quality to those heard in spasmodic asthma, but occur with inspiration and not, as a rule, with expiration.

Another point, and an important one, is the care with which morphine especially, and the vascular antispasmodics, should be used to control the acute pain during an attack of angina pectoris. In certain cases an injection of morphone is the only thing that will give relief from this agonizing pain, but the physician should recognize the fact that there is a certain amount of danger attached to the ad-
ministration of it in a certain proportion of these cases. Sir R. Douglass Powell says that it is con-
traindicated in angina pectoris if the kidneys are markedly involved, but this has not been my ex-
perience. If it is known, or suspected, that the patient has been suffering for any length of time
from supertension, it is not unreasonable to assume

\[ \text{ministration of it in a certain proportion of these cases. Sir R. Douglass Powell says that it is con-
traindicated in angina pectoris if the kidneys are markedly involved, but this has not been my ex-
perience. If it is known, or suspected, that the patient has been suffering for any length of time
from supertension, it is not unreasonable to assume that a certain amount of change has taken place in
the walls of the bloodvessels, and especially the aorta, and that the blood has been weakened in spots. The
effect of the morphine here would be to suddenly
dull the sensibility of the nerve centres, thus
eliminate the reflex protective phenomenaf, and
produce sudden death by rupture of a weakened
spot in the aorta. Personally, I have had two just
such very unpleasant experiences through the use of
morphine. Both of these patients died soon after
the morphine was given, and both with all the
symptoms of air hunger and internal bleeding.
One of these patients, a physician, I had been able
to observe for a number of years, and knew that
his arterial tension had been over 220 mm. Hg. for
at least two years. The other was a woman of
fifty-five years of age to whom I was called for
the first time to relieve an attack. From inquiry I
felt sure that she, too, had been suffering from su-
pertension for some time.

Report of a Case.

BY ALEXANDER STERLING, M.D.

Philadelphia.

Physician to Outpatient Department of the Jewish Maternity Hos-
pital; Clinical Assistant in Children’s Department, and in Ear,
Nose, and Throat Department of Mount Sinai Hospital.

History. Mrs. C. C., aged twenty-nine years. Married
eight years; two children. Past history negative. Third
pregnancy. Felt worse during this pregnancy than in
the previous two. She could not walk. Had much pain.
Motions of fetus in utero were very weak, two or three
days passed without a movement, otherwise
normal. August 15th, 11 a.m., she was in active labor,
normal presentation (left occipitoposterior). August 6th,
3 a.m., she gave birth to a baby girl; delivery normal except
that I had to rupture the membranes after the delivery
of the head. A half hour later the placenta was delivered;
on examination the cord and membranes were found normal.
The uterus contracted firmly, but was rather large, but
nothing to excite suspicion. Daily visits were made. The
uterus was firmly contracted. The lochia were normal, but
very little after second day. Some after pains. On
the seventh day she was out of bed. On the eleventh day
she felt some pain, as she had expressed it “something
wanted to come out.” She was getting worse; had sharp
pains the whole night. The next morning she took a hot
douche and while over the basin she passed a large mass
—the size of a thrice month miscarriage—as one of the
old ladies described it. I found the patient sitting on the
bed very much frightened. There was no hemorhage;
the temperature and pulse were normal. The mass was
lying in a basin. It had no odor, was like a big bag com-
pletely closed up floating on the water, being a dull grayish
white in appearance, and soft and mushy to the touch.
With a toothpick I tore open the bag. It was empty, but
at one side there were bloodvessels which appeared to be
organized but which were not, and some bloodvessels
branching in all directions. There was nothing inside the
bag which resembled an embryo in an undeveloped stage.
After assuring the patient that she was not in any danger
I summoned Doctor Longacker, who after carefully ex-

PRIZE QUESTION NO. CXXXVIII.

THE TREATMENT OF INSOMNIA.

(Continued from page 874.)

Dr. Morris Ginsburg, of Philadelphia, Pa., says:

For therapeutic purposes, the subject of insomnia
may be considered under several heads:
1. That due to organic disease, with pain as the
   predominant causal factor.
2. Infectious processes and intoxications either
   exogenous or endogenous, acute or chronic.
3. Functional conditions resulting, perhaps in part, from general constitutional disorders.

In the first class of cases, insomnia results from some real, demonstrable cause—a malignant condition, cardiac disease, a fracture—this in turn giving rise to pain, cardiac distress, or dyspnea. If the condition is acute, if the pain or distress is intense, if the disease is hopeless, and if various other manipulations (as in the case of fracture) are without avail, it is vain to temporize. Morphine is the drug to be used, as such, or in the form of one of the various opium preparations. Morphine is the most powerful analgesic, and in heart cases it is specially applicable, because of its undoubted cardiac stimulating property. Respiratory stimulants, however, such as strychnine, atropine, caffeine, may also serve the same purpose. On the other hand, if the pain is not so severe, if the disease is to be long drawn out, and death is not the inevitable end, morphine is the last drug to be employed. We must first exhaust all the other means of treatment.

Under the second subdivision I place the acute infectious disease, the diathetic or constitutional disorders—diabetes, rheumatism, gout, etc., gastrointestinal, biliary and other endogenous intoxications, as well as those due to drugs—alcohol, tobacco—and occupational surroundings.

Insomnia, under such conditions, comes from the introduction into the system or from failure of elimination from the system of poisonous material. Indications therefore are clear. Increase elimination through all possible channels. The gastrointestinal tract must be made active by persistent catharsis, the urinary system should be aided particularly by the most potent and least harmful of diuretics—water—and in sufficient quantities, either by mouth or by rectal instillation. Elimination by the skin should be furthered by frequent bathing or, as in some instances of the acute infections or in uremic conditions, by hot packs. In the more chronic diathetic diseases, regulated exercise, massage, proper diet, and other measures to be elaborated upon, should be used.

I have left the use of drugs for the last, because their action is temporary, and in long continued cases lead to habit formation and to cumulative symptoms. For temporary use, however, coupled with judicious handling of the case by other modes of treatment, drugs should be considered. Begin with the mildest, such as the bromides, either given in regular small doses throughout the day or in larger doses of from twenty to thirty grains at night. Sulphonal and trional, from five to twenty grains, or veronal, from two to ten grains, are also very useful in this class of cases. They have a tendency toward a cumulative effect if used continuously for several weeks, with consequent disturbing and, at times, dangerous symptoms. Their administration, therefore, and for that matter the use of all forms of hypnotics, should be intermittent.

In the acute infections, insomnia may be quite marked and may even lead to delirium. Warm baths may be given and drugs more powerful in their action than those above mentioned, may be necessary. Hyoscine very often serves admirably—particularly in the small doses of from 1/500 to 1/200 grain, repeated several times. Bromides and even chloral, the latter in doses of from five to ten grains, and guardedly administered, become essential in some cases, as in insomnia and delirium from alcohol, while in others, nothing but morphine, with or without hyoscine, will produce a maximum effect. I do not wish to encourage an undue use of opium, but in cases of pneumonia with labored breathing and with pleuritic pain, it is the drug first in my mind, the more so since I am convinced that the heart is strengthened either directly or through the relief of the distress. Insomnia from gouty or rheumatic conditions will yield to the salicylates, to aspirin, or aspirin and codeine.

We now come to the third class of cases, the one which includes the greatest number of sufferers. Insomnia from neurasthenia or hysteria, from bodily fatigue, from improper living, improper food, bad hygiene, lack of exercise, from nervous exhaustion due to mental strain and business worries, household cares coupled with an unstable personality or mentality.

From this enumeration of causes spring indications for treatment. One very important factor must be borne in mind, namely, that if the physician does not relieve the patient quickly, he will be relieved of the patient who will drift to someone else. Long and patient study of the case, of the habits and surroundings of the individual, is frequently necessary before proper therapeutics can be applied. First, therefore, get the patient's confidence by prescribing veronal, sulphonal, trional, bromides, or paraaldehyde, in suitable doses to produce sleep. Then examine the patient methodically. Are there any gross organic faults? Is there any generalized intoxication from one or another source? Is there evidence of any constitutional affection, or is the patient merely anemic, complaining of headache, fatigue, lack of energy, and poor appetite? Examine the urine. Are there any kidney lesions, or is there only a deposition of urates, phosphates, uric acid, or calcium oxalate crystals? Ascertain the reaction of the urine, and if it is abnormal, attempt to correct it by the alkalies—if too acid—or by boric acid, hexamethyleneamine, etc., if alkaline. Examine the blood for signs of chlorosis, perhaps pernicious anemia, basophilic degeneration, and for malaria.

Then enter into the details of the patient's daily mode of life, the time for work, for food, and for recreation, the amount of time spent outdoors, the hygiene at home and at the place of employment, the character of the food and drink. There is nothing so efficacious as a definitely prescribed form of spending one's day. Have him awake early in the morning, take a cool or lukewarm bath, go out for a little walk, eat a wholesome and not too heavy breakfast, go to work or to the office, take a rest after the midday meal, go back to the work, avoiding if possible any too great mental strain. A little exercise during the afternoon is useful if obtainable. After the evening meal again take a rest, then indulge in some form of exercise out of doors, take a warm bath, a little massage, drink a cup of warm milk, and go to bed early. In
the case of a woman fatigued by household work and worries, a partial rest cure, together with mild forms of exercise will be useful. Avoid all liquors, tea, and coffee, particularly before going to bed. Make the last meal of the day rather light. Do not allow the mind to work upon complex problems. In other words, live a "simple" and hygienic life.

The various drugs used should be interchanged from time to time, and occasionally, after the patient's confidence has been obtained, I have been in the habit of prescribing one tenth grain of calomel with results as marked as from the administration of one quarter grain of morphine. This is true chiefly in functional cases, but at times even real pain may be allayed by some such placebo. Morphine should never be given. It is nauseating, constipating, habit forming, and demoralizing to this class of insomnias. In the meanwhile, if necessary, use general eliminative treatment, correct what ever defect may be ascertained by careful physical examination, and the great majority of the host of insomnia complainers will be cured.

Dr. Leonard Keele Hirshberg, of Baltimore, Md., says:

It has been said of books but it may also be said of sleep theories that of the making of them there is no end! Howell, Sidas, Ribot, Coriat—but why name them here when there are so many who propose theories of sleep? Multitudinous though they be, they fail to explain or to cure insomnia. I have one patient, Mr. G. L., aged fifty-six, who has been a victim of sleeplessness for thirty years. He has read every theory, every book, every article, visited every land, and consulted thousands of doctors—yes, even better ones than I am!—yet he is not cured.

Insomnia is more easily treated than cured. Not that it goes always uncured, but because relief often is the better part of valor. Far be it from me to throw cold water on any insomnia cure! That is not my purpose. It is a question usually of discovering rather the underlying cause, the motive, or the malady that causes the disorder and then of removing that, in lieu of curing merely the symptom of sleeplessness.

If insomnia is due to arteriosclerosis—and this be it remembered is an independent disease from the often associated symptom of high blood pressure which is frequently absent—measures directed toward reducing the hardness and rigidity of the vascular deposits as well as softening the arterial tubes, may help to bring sleep. It required as high as seventy-five grains of potassium iodide to put one such sufferer to sleep at night.

If the insomnia is due to certain kinds of neurotic, hysterical, or sexual traumata, a patient course of treatment which includes psychoanalysis and Freudian dream interpretation may prove effective. Three such patients have in the last two years been relieved of sleeplessness.

Another common type of insomnia is the public official whom the newspapers are hunting. He and the business man whose industry is in trouble become afflicted with an insomnia that, like many others, must first be polished down with veronal, paraldehyde, medinal, sulphonal, trional, chloral-amide, or one of the other hypnotics. All sleep inducing drugs should be eschewed if possible. Since most of these, especially veronal, lower the blood pressure, and the mental tension which has sent the arrow near 200 mm. Hg. in part responsible for the insomnia, the reduction pressure soon brings sleep. Morphine should never be used nor any habit forming drug except, perhaps, in the insomnia that is associated with valvular heart diseases. Curiously enough, insomnia with low blood pressure is often benefited by strychnine and lime salts. There is no doubt about this. Regularity of habits, change of scene, seashore, mountain, and hydrotherapy all help.

Perhaps after all is said and done the easiest ways are the best. The victim must be made to understand that insomnia is a bad habit to be broken. Beds, pillows, furniture, and rooms must be changed about. Low pillows must be made high. Light bed covers must be made heavy. Food at night must be stopped, or begun in some instances, hot drinks, hot baths, massage, light rubs, gymnastics, galvanism, and exercises must be started. Insomnia is often broken up by the effort of being able to sleep at night. I have helped at least one patient by an enema of hot saline. Purging and dancing, gymnastics and rest, card playing and silly vaudeville, each play a part in the treatment of insomnia according to the tissue caprices of the individual patient. As in all other aberrant conditions of health, each patient is more or less a law unto himself. The "wee bit of a night cap" that puts my father to sleep may mean a wretched night to another. The wet sheet and cold pack that soothes one patient may spell chloral to another. Strophanthin has played the part of Morphes to several heart sufferers with auricular fibrillation.

Dr. W. T. Parrott, of Kinston, N. C., says:

The first thing to do is to determine the actual existence of insomnia. Patients often apply to the physician complaining of insomnia when it does not really exist and no treatment should be attempted until this is proved, in doubtful cases it may be necessary to have the patient watched in order to make sure of the actual existence of the condition. In no case should the patient be aware that he, or she, is under observation. Now it is a physiological fact that the loss of sleep for three weeks means death, although it is not unusual for a patient to tell the medical attendant that they have not slept a wink for six weeks or more. The selection of the person to make the observation is important because not only the quantity but the quality of the sleep should be noted. Every possible cause tending to prevent sleep should be noted. In the day time the habits of the patient should be watched. His occupation, aims, ambitions, food, drink, exercise, tobacco or other drug diversions, association and the manner in which he spends his evenings. His worries and secret passions may be the fons et origo. Fear of impending trouble or even fear of death often keeps some patients awake. A removal of any of these causes is a cure for the insomnia. The physician should carefully examine every organ for a possible cause
and he should not forget that insomnia is an early symptom of many diseases, and a correction of this is the treatment. I believe that simple insomnia per se is a very rare condition except in so far as it is that of a habit. Most often it is a symptom complex and dependent upon an underlying cause which must be treated. A successful treatment therefore, is a treatment of the underlying condition. In the nervous system we very often find a cause and sometimes a treatment.

In neurasthenics we find two grand subdivisions as to cause, first, those of a true nerve exhaustion; second, the neurasthenic proper. Those due to true nerve exhaustion require rest, and a change of climate is often beneficial. Care should be exercised in sending a patient away. I much prefer to send a country man to the city and a city man to the country. In other words my best results have been obtained from a real change of scene. A neurasthenic proper should never be sent away. He never should be advised to rest. My best results have been obtained by putting him at hard work, with little or no time to think of himself. In so far as it is possible I advise rapid diversion and much play for him, and I am not careful as to the kind.

Hydrotherapy. To meet an immediate indication of sleep, hydrotherapy is the best measure with which I am acquainted. While for a majority of patients a hot bath is indicated, still there is a group which do better with a cold bath. Technic is important and there is not sufficient time to discuss it.

Cola. For that class of patients who are very weak and unable to take sufficient exercises to produce sleep, I have found the use of cola of much value, the patient going to sleep immediately after a sufficient amount of exercise was gone through with.

Electricity. I have applied all forms of electricity and am decidedly more impressed with galvanism properly used.

Placebo. For that class of neurasthenics who are very susceptible a placebo at night is often sufficient. Massage is one of the very best non drug agents, but like the hot bath, it sometimes produces sleeplessness.

Hypnotism. In some cases it acts admirably and I have never seen any harm produced from it.

Drug treatment. As to drugs in insomnia I have never applied them except as a dernier ressort, and then only with a great deal of care. I should much prefer to have my patient an insomnomaniac than a drug fiend. Still in selected cases and with proper drug selections they are sometimes valuable accessories. In insomnia, due to great mental shock or mental perturbation, a full dose of sulphonal or chloral, or one hundredth of a grain of hyoscine have in turn given me good results.

If sulphonal is selected I prefer to give it with an equal part of trional as the immediate effects of the latter are obtained and these are later reinforced by the more persistent and lasting effects of the sulphonal. In that form of insomnia, in which sleep is qualitative instead of quantitative, drugs should never be applied. Chloralamide has some advantage in insomnia due to pain. Paraldehyde is a reliable and safe hypnotic, but its disagreeable odor prohibits its use for most patients. Chloroform is risky and should never be administered. Urethane has nothing to commend it, but it may be used as a change. Veronal in my hands has proved safe and dependable and in every instance devoid of bad aftereffects. Ten grains is the average adult dose and will give the patient two nights’ sleep. I do not favor a smaller dose. In a general way I prefer veronal to any other hypnotic and use it in a routine way provided, of course, there is no contraindication for drug administration.

Ether in the Treatment of Infections.—Souligoux, in Tribune médicale for April, 1913, states that since witnessing recovery without amputation in the case of a man with both legs mangled by a heavy dray, ether having been freely used to cleanse the wounds, he has been employing this agent in the treatment of all wounds and superficial infections such as lymphangitis, erysipelas, etc., with excellent results. In lymphangitis of the upper extremity, for example, the limb is first washed with soap and water, as though for operative work, the skin then dried, and the involved region covered with compresses, upon which ether is copiously poured. Impervious material is finally applied, with bandages holding it, most tightly at the two ends of the dressing, and the whole covered with thick cotton wadding, further to lessen evaporation of the ether. In hundreds of cases thus treated only favorable results were observed, and many cases of serious infection recovered.

In peritoneal infections Souligoux was led to employ ether by his experience in a case of intestinal obstruction of eight days’ standing in which, at operation, perforation was found and the peritoneal cavity filled with fecal material and gas. After suture of the perforation, the peritoneal cavity, including the pelvis, was freely irrigated with ether, careful sponging practised, two drains inserted, and an artificial anus instituted. The patient promptly recovered, and since that time the author has used ether in all abdominal operations with suppuration, with obvious success. Marcille, working under the author’s direction, has used ether in six cases of ruptured ectopic gestation, seventeen cases of strangulated hernia, three of abdominal wounds with intestinal perforation, three of diffuse peritonitis, and one of perforated gastric ulcer, recovery following in all these except one case of very severe abdominal traumatism, and one of peritonitis. In a case of compound fracture of the bones of the forearm, with deep soiling of the wound, healing took place by first intention after irrigation with ether and immediate suture. The volatility of the ether appears to favor its penetration into all recesses of deep wounds, thus insuring satisfactory disinfection. On the peritoneum no harmful effect could be noticed, the gut merely acquiring a pink color and undergoing contraction.
Uses of Sodium Citrate in Dyspepsias.—Plieque, in *Bulletin médicale* for May 31, 1913, states that sodium citrate appears to exert, in the treatment of dyspepsia, several beneficial actions. In the first place, it facilitates the digestion of milk when a milk diet is being given, preventing the formation of large, compact clots where the fluid is drunk too quickly or in excessive amounts at one time. Variot showed that many cases of infantile dyspepsia, such as occur so often in bottle fed infants, yield when a tablespoonful of the following solution is added to each four ounce (120 gramme) bottle full of milk:

R.  
Sodii citratis, .................. gr. xxx (2 grammes);  
Sodii bicarbonatis, .......... 5i (20 grammes);

Solve.

Again, sodium citrate acts as an alkali, and as such, becomes a soothing agent in cases of pyrosis, besides diminishing gaseous fermentation and even obviating the regurgitation of food.

Finally, sodium citrate, even in small doses, is a very good laxative. In combating constipation, so frequent among dyspepsics, it lessens autointoxication from intestinal fermentative processes and obviates the mechanical disturbances resulting from the accumulation of gases. In constipation associated with hepatic congestion, Huchard frequently advised its employment, along with sodium sulphate and bicarbonate:

R.  
Sodii bicarbonatis, .......... 5v (20 grammes);

Solve.

Even if given without the sodium sulphate, sodium citrate acts quite sufficiently as a laxative.

Treatment of Chloasma.—Dalché and Fouquet, in *Nouveaux Remèdes* for August 4, 1913, is credited with the following preparation, to be applied to the parts at night on muslin:

R.  
Emplastri plumbi, .......... 3i (12 grammes);  
Styracis, .......... gr. xxiv (1.5 grammes);  
Cere flavae, .......... 5i (0.5 gramme);  
Fleis liquide, .......... 3x (40 grammes);

M. Ft. unguentum.

Next day the following ointment should be used over the pigmented areas:

R.  
Bismuthi subcarbonatis, .......... 5i (12 grammes);  
Kaolinii, .......... 3i (10 grammes);  
Petrolatii, .......... 3x (40 grammes);

M. Ft. unguentum.

Or, the following mixture may be painted over the parts morning and evening:

R.  
Ammonii chloridi, .......... 5i (4 grammes);  
Acidi hydrochlorici diluti, .......... 5i (5 grammes);  
Glycerini, .......... 5i (30 grammes);  
Lactis, .......... 5i (50 grammes).

Misc.

Or, again, the parts may be rubbed over twice daily with:

R.  
Zinci oxidi, .......... gr. v (0.5 gramme);  
Hydrargyri oxidi flavi, .......... gr. ii (0.15 gramme);  
Olei theobromatis, .......... 5i (20 grammes);  
Olei ricini, .......... 5i (20 grammes);  
Olei rosei, .......... 5i (20 grammes);

M. Ft. unguentum.

The general treatment in these cases should consist of organotherapy, either in the form of ovarian extract alone, or better, by the simultaneous administration of ovarian and adrenal extracts.

Treatment of Hiccough.—R. Oppenheim, in *Progrès médical* for June 14, 1913, discussing the palliative treatment of hiccough in cases where it persists, notwithstanding apparently appropriate treatment of the original cause, or the cause cannot be found, states that among the empirical procedures most likely to arrest the disturbance are pressure upon the wrists, of the ulnar nerve in its recess at the olecranon, and especially of the phrenic nerve in the neck; the application of a mustard plaster or the hot iron to the epigastrium; slow deglutition of fluid while holding the nose closed; a serious of rapid and deep inspirations (Mathieu); prolonged extension of the tongue out of the mouth (Lépine); temporary suspension of breathing in the position of inspiration or forced expiration, and compression of the epigastrium with the hand or a tight bandage.

In all cases any nervous excitement present should be subdued. Where the general condition permits, the least measure is a tepid bath, 35° C. (95° F.), lasting from one half to one hour. The following preparation should be simultaneously administered:

R.  
Atropine sulphatis, .......... gr. 1/12 (0.005 gramme);  
Morphine hydrochloridi, .......... gr. iss (0.1 gramme);  
Aque chloroformi, .......... 3i (10 grammes);

M. Sig.: Three drops to be taken every two hours in a little water.

Another suitable combination is:

R.  
Potassii bromidi, .......... 5i (0.5 gramme);  
Aque laurocerasi, .......... 5i (0.5 gramme);  
Aetheris, .......... 5i (6 grammes);  
Syrupi, .......... 5i (30 grammes);  
Aque distillate, q. s. ad .......... 5v (150 grammes);

M. Sig.: One tablespoonful every hour until the attack ceases.

In reflex hiccough of gastric origin, one of the most frequent forms, prompt benefit is often obtained from the following preparations, recommended by Robin in cases of "hypersthenic" dyspepsia:

R.  
Picrotoxini, .......... gr. 1/6 (0.05 gramme);  
Alcoholis, .......... q. s. ad solv.;  
Morphine hydrochloridi, .......... 1/2 (0.05 gramme);  
Atropine sulphatis, .......... 1/6 (0.01 gramme);  
Extracti ergote aquosi, .......... 1/6 (1 gramme);  
Aque laurocerasi, .......... 5i (12 grammes);

M. Sig.: Five drops every four hours.

To relieve the epigastic pain accompanying hiccough, the following powders should be prescribed:

R.  
Sodii bicarbonatis, .......... 5i (0.5 gramme);  
Saccari lactis, .......... 5i (0.5 gramme);  
Magnesii oxidi, .......... gr. xxii (1.5 grammes);  
Crates praeparatae, .......... 5i (0.5 gramme);  
Bismuthi substilatis, .......... 5i (0.5 gramme);

M. Sig.: One powder in a little water upon the advent of pain.

Persistant hiccough in children suggests intestinal helminthiasis, to the elimination of which treatment should be directed. In nurslings, on the other hand, hiccough suggests overfeeding. Rather than administer special mineral waters or sodium citrate, one should try to prevent the hiccough by strict regulation of the feeding.
from, with a view to increasing this efficiency and of preventing waste. Nearly one hundred tons of high grade carnitite have already been procured from the claims in Paradox Valley, included by experts among the richest radium bearing regions in the world.

Doctor Parsons asserted that not one cent of the radium to be extracted would be for sale; that every milligram of the metal would be used in the cause of humanity in the treatment of cancer, and that the United States Bureau of Mines had evolved an entirely new method of extracting radium chloride which would reduce the cost materially. Finally, he stated that clinics for the treatment of the afflicted would be opened in the Memorial Hospital of New York and in Doctor Kelly's own hospital in Baltimore. We hope that means will be found through which the entire country will be able to receive the benefits of this great philanthropy, which, through the distinguished physician who is its initiator, will reflect great credit upon the medical profession as a whole, while proving of incalculable benefit to sufferers of the most dreaded of all diseases.

THE BALKANS AND THE HEALTH OF THE WORLD.

Unable to prevent the war, powerless to control it, and impotent to end it, in the Balkans, the great powers have scored at least one triumph—the prevention of epidemic disease diffusion throughout the rest of the world—as the result of strife on a tremendous scale. This great achievement of preventive medicine completely eclipses any of the accomplishments of a united European diplomacy during the same period. Although the war is at an end, and much good work has been done in the way of limiting the spread of certain diseases, there still remain for solution many important sanitary problems before the health of the world, with respect to the consequences of the Balkan combat, can be definitely assured. In order that this safety may be secured it is necessary that some agreement be entered into between the powers and the allies; among the allies themselves; between each of the allies and Turkey; between the powers, the allies, and Turkey on all sanitary and health questions.

The Balkan war differed in no wise from the wars of the past—pestilence scored as heavily as nicked bullets; faulty hygiene decimated regiments with a precision deadlier than that of machine guns; and famine claimed its quota of victims—save that, except in remote instances, the health of the outside world was never seriously endangered. Herein lies the large triumph of the great powers, nay, the
triumph of modern preventive medicine. Among the combatants themselves, however, disease was most active. Cholera claimed more than the sabre; typhoid fever still maintained its reputation as the “destroyer of armies”; and dysentery and typhus exacted their usual toll of human lives. Plague did not ravage any of the armies to a marked extent, though conditions were apparently ideal for the disease. The explanation of this seeming anomaly is that plague is not as a rule of frequent occurrence as long as armies keep moving in either attack or retreat. The one way to get rid of plague is to camp out, and away from the focus of infection, and should the disease reappear, to again strike camp and proceed farther afield. Active campaigning is a decided prophylactic, and never was this fact better illustrated than in the Balkan war.

During the period of the peace conference, and while diplomats at St. James were arguing over the creation of a New Albania, and while troops were resting on their arms, disease exerted its greatest fury. It was the oft repeated experience of idle troops in the field and disease; it was the same with American troops at Chickamauga and Montauk; it was the same with the British soldiery on the African veldt; it was the same with the Japanese and the Russians after the fall of Port Arthur; and, unfortunately, it seems it will be ever thus.

Under the new order of things, under changed geographical and political conditions, the work of the European powers, in the interest of humanity, has just begun; and while striving for world peace world health must not be neglected. Out of the Balkan chaos diplomacy is on trial, but over and above all considerations of strategy and ambition loom up the questions of the health of the world, and to the sanitarians of Europe may we look with confidence for the discharge of their full share in the work for mankind.

THE MENACE OF MENTAL DISEASE.

For years the medical profession has stood a unit for the preservation and protection of individual life and happiness and the welfare of society. Through its efforts one bulwark after another has been erected to protect the citizens of the United States from physical infection and from mental and moral contamination by the admission of physically, mentally and morally unfit immigrants. In the fight against physical ailments the people at large fully realize the importance of the protection afforded through proper quarantine regulations. The fear of cholera, of plague, and of similar physical affections is so great and so widespread that no health officer of the port of New York would be tolerated in office who failed to enforce proper regulations for the prevention of the admission of persons infected with these diseases.

Mental disease and inferiority are not less potent factors in bringing about national decay and national disaster than are such diseases as cholera and plague. The only difference is that they act less rapidly and their effects are less easily observed. Under the leadership of Dr. Carlos MacDonald and his successors the State of New York has built up a system of safeguards for the exclusion of the alien insane which has hitherto been most efficient. But the organization which has been brought to a high state of efficiency for this purpose is being made the prey of cheap political grafters.

The testimony in the recent impeachment proceedings revealed that the administration of the Hospital and Immigration Service, an efficient and highly developed organization, has been tampered with. There have been removals made ostensibly for the good of the service. There has been a cry of economy raised in the State Hospital Service. With the present management of the Alien Deportation Bureau before us such changes prompt an inquiry as to whether they have been made really for the good of the service, as asserted, or whether they have been made in the course of an effort to provide governmental pay for political henchmen. The safety of the public demands that the acts of the recently impeached governor be reviewed and any unfit appointments made by him revoked.

SOME OF THE LEGAL ASPECTS OF BLOOD POISONING.

While in the class of cases in which this condition occurs as a result of operations the infection is generally introduced from without by unclean fingers or instruments, in some instances infection takes place in spite of the utmost endeavors to maintain aseptic conditions, and the most melancholy examples of this kind have been those where skilled and careful surgeons have themselves contracted fatal septicemia in operating. The dose of the poison may be exceedingly small; yet some of the most fulminating cases have followed a very slight prick of the skin—showing in these instances the extremely toxic character of the virus. As to whether the latter finds entrance at once into the blood, or indirectly and later by the lymph stream, it would seem probable that either event may occur, and, as Victor Horsley says, if this be the case, it offers some explanation of the difference in the incubation period in different cases. A living, rapidly growing virus may easily be understood to
multiply and spread through the meshes of connective tissue and along the channels of lymphatic vessels, although only a very small quantity may have lodged in the wound. An important element in determining the period of incubation, as well as the severity of the disease, is the degree of efficiency of the resistance afforded by the lymphocytosis at the point of entrance. All such matters may have to be taken into consideration in some of the cases which come up from time to time in the courts.

There are also other cases of blood poisoning besides those from wound infection in which civil suits are brought, and the legal aspects of the subject may truly be said to be varied and of great importance. At the October meeting of the Society of Medical Jurisprudence, at which Dr. A. Ernest Gallant presented the medical aspects of blood poisoning, Mr. James Taylor Lewis, counsel to the New York State Medical Society, made an address in which its legal aspects were well brought out. In the class of cases having to do with the abdomen he said the two most common were appendicitis cases and those of pyosalpinx, the pathologic condition being in the great majority of instances of the latter due to gonococcus infection. In one case to which he referred a suit for $50,000 damages was brought against a surgeon who had left in the abdomen of a patient one of the large gauze pads employed to "wall off" the seat of operation. At first, Mr. Lewis said, it looked to him as if the surgeon were altogether culpable, but a careful examination into the facts of the case convinced him to the contrary. Both lawyers and physicians should "get to the bottom of things"; and in this connection he criticized his legal confreres for too often failing to acquire such intimate knowledge of all the attendant circumstances in their cases as, in justice to themselves and their clients, it was their duty to obtain. In the case in point the legal aspects were shown in the questions: Is it a proper precaution to number the instruments, gauze pads, and other matters used in operating? Were they here so numbered? Were they all accounted for? Are the nurses the agents of the hospital or of the surgeon? A different kind of case related was that of a man who suffered from a very severe colon bacillus infection resulting from the application of cow dung (which some one had told him was "good for a felon") to an open incision which his physician had made in treating an inflammation in a finger caused by an injury. He sued the physician for $25,000, but at the trial the lawyer who had been the plaintiff's adviser did not have the hardihood to appear. He had to plead his own case, and it is needless to say that he lost.

**APPARENT CURE OF RABIES.**

It is a matter of general knowledge that, apart from the Pasteur treatment, our means of helping the unfortunate victim of rabies are virtually nil. And even with the Pasteur method we are often doomed to failure because we do not recognize the existence of infection sufficiently early, for, after the onset of symptoms a cure can scarce be hoped for. We can, therefore, heartily welcome such an experience as James H. Haberlin records under the title quoted in the *New York State Journal of Medicine*, September, 1913.

The first patient was bitten in the face by a rabid dog five weeks before the onset of symptoms, and, in spite of all that could be done, death ensued a few hours after the beginning of treatment. Some three days later a second patient, a dog catcher, came under observation, having been bitten in the leg five weeks previously by the dog that bit the first patient. After stabling his horse at 6:20 in the evening of the onset of symptoms he walked three quarters of a mile to his home. Shortly after entering he went to bed, displaying for the first time considerable emotional excitement. In a few minutes he began crying and gesticulating violently, clutching frantically at his throat as if to relieve some obstruction. He seemed conscious and oriented, and seemed to realize his trouble, for he would try to drink, always without being able to swallow, and then would grasp his throat and nod his head as if trying to tell those present of his difficulty. His condition rapidly grew worse and he became maniacal and began to spit continuously. The clonic spasms of his pharynx continued, finally becoming tetanic and threatening suffocation. This was at 8:30 in the evening and at this point our author entered upon the scene and began the treatment which seems to have been responsible for the cure of the patient. He began by injecting ten c. c. of a one per cent. aqueous solution of phenol into the subcutaneous tissues of the abdomen. In half an hour ten c. c. of a two per cent. solution were injected, and this dose was repeated in an hour. By 11 p. m. improvement in the patient's condition was very perceptible. Hourly doses of ten c. c. of the one per cent. solution were then given until a total of 1.5 grammes of pure phenol (twenty-two and a half grains) had been administered. Six hours after the onset of the treatment the patient began to grow somnolent, and when aroused was able to swallow easily. At this time—2 a. m.—it was learned from the patient that he remembered nothing from the time of his stabiling of his horse. The treatment ended at this point and in four days the patient was

*New York State Journal of Medicine, September, 1913. p. 483.*
out of doors, resuming his work on the sixth day.

Haberlin says that he was led to use phenol subcutaneously in the treatment of this patient on the basis of Guido Baccelli's reported cures of tetanus by the same means, and by the fact that there is apparently so close a resemblance between tetanus and rabies. He seeks to explain the action of the subcutaneous injections on the grounds of the well known selective affinity of phenol for nerve tissue, its loose union with cell protoplasm, and its firm combination with bacterial substances. On account of the fact that phenol does not act to precipitate albumins in the manner of the ordinary precipitants, and because it is rapidly taken up from the point of injection into the lymph and blood it is possible to give the large quantities of such concentrated solutions as were used without causing any unfavorable local reaction.

Attention is called by Haberlin to the fact that this single case proves nothing so far as the treatment of the disease is concerned. Though recoveries are very rare, it is believed that the disease is not strictly one hundred per cent. fatal in man. In this case also the fact that the patient had been bitten a number of times before by suspicious dogs cannot be totally dismissed, on account of the possible acquisition of a certain degree of immunity. "Everything connected with the recovery in the case is a subject for pure speculation at this stage of our knowledge, or lack of knowledge."

The scientifically conservative attitude of the author toward the results he reports is in refreshing contrast with the usual eagerness with which such a phenomenal record would have been heralded by many an author. This very conservatism inclines us to devote so much attention to his possible invaluable addition to our knowledge of the treatment of rabies. Moreover we would call attention to the fact that phenol was recommended by Déclat (Traité de l'acide phénique, page 544, fourth edition, 1874) in 1865 in the treatment and prophylaxis of this dread disorder.

PUNISHMENT FOR SUBSTITUTERS.

We have taken occasion from time to time to point out the evils of substitution, both from a moral and from a medical standpoint, and it is interesting to note that the practice of furnishing something other than is ordered by the physician seems to be on the decline. This is no doubt due largely to an ethical awakening on the part of dispensers. The enforcement of the National Food and Drugs Act has been a very important factor in stimulating the conscience of the people as a whole. The discussions incident to the enforcement of this act have aroused the moral sense of the people to a keener appreciation of their duties in every direction. The leaders in the drug trade are fully aware of the grave responsibility resting upon the pharmacist and the dispenser and have done much to arouse pharmacists to a just appreciation of these responsibilities. The increasing severity of the sentences imposed upon prisoners found guilty of substitution has also been an important factor in discouraging this evil practice. In New York a substituter was recently sentenced to three months' imprisonment. Nor is this an isolated instance, as prison sentences have been imposed in several cases of this kind during the past few years. This subject is one that vitally interests the physician, for unless his prescriptions are filled as written he cannot hope to achieve the desired results. It is to be hoped that the courts will continue the imposition of severe sentences for crimes of this kind.

OBITUARY.

ALEXIS MARCY LEON, M. D., of New York city.

Dr. Alexis Marcy Léon died on Sunday, November 2nd, in his home at 70 East Fifty-sixth Street, New York city. Born in New York city on March 25, 1857, he was educated in letters at Manhattan College, receiving the degree of A. B. cum laude in 1875, and the degree of M. A. shortly after; and in medicine at the College of Physicians and Surgeons (medical department of Columbia University), receiving his M. D. in 1878. After being graduated in medicine he served as interne at Charity (now City) Hospital until October, 1879, when he succeeded to the extensive practice of his father, the late Dr. Alexis Léon, an eminent physician who numbered among his clientes many of the best known families in the city.

He was a member of the Medical Society of the County of New York, the Medical Society of the State of New York, the American Medical Association, and the Alumni Association of the City Hospital. He was for many years visiting physician at St. Francis' Hospital.

He was an old subscriber to this Journal and also a valuable contributor. Doctor Léon died suddenly, after a short illness, of heart disease. He is survived by his widow, a son, and five daughters.

NEWS ITEMS.

Changes of Address.—Dr. Warren S. Simmons and Dr. A. Sutherland Miller, to 20 Gates Avenue, Brooklyn. N. Y.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.—At the annual meeting of this association, held in New Orleans on Thursday, Friday, and Saturday, October 23rd, 24th, and 25th, the following officers were elected: President, Dr. D'Orsay Hecht, of Chicago; first vice-president, Dr. W. W. Butterworth, of New Orleans; second vice-president, Dr. Willard J. Stone, of Toledo, Ohio; secretary, Dr. Henry Eno Tuley, of Louisville, Ky. (reelected); treasurer, Dr. S. C. Stanton, of Chicago (reelected).
A Meeting of Neurological Societies.—A meeting of the Section in Neurology and Psychiatry of the New York Academy of Medicine will be held in conjunction with the New York Neurological Society on Tuesday evening, November 11th, at the Academy of Medicine. The program will include the following papers: Concerning the Hypophys, by Dr. Frederick Tilney; Some Causes of Disappointment in Operations on Brain Tumor, by Dr. William G. Spiller, of Philadelphia. The papers will be illustrated by lantern slides.

New York Division of the Reserve Corps of the Army.—The annual banquet of the New York Division of the Medical Reserve Corps of the United States Army, which is composed of New York physicians who are on the inactive list in that branch of the Service, will be held on the evening of Saturday, November 8th, at the Hotel Savoy. Lieutenant Colonel Alfred E. Bradley, Medical Corps, United States Army and Dr. Simon Baruch, professor of hydrotherapy at Columbia University, will be the guests of honor. It is expected that there will be a good attendance of army medical officers stationed in and around New York. Dr. Henry C. Coo, professor of gynecology at the University and Bellevue Hospital Medical College, will act as toastmaster.

National Radiological Institute was incorporated recently in Baltimore with the following officers: President, Dr. Howard A. Kelly, of Baltimore; vice-president, Dr. Curtis F. Barnum, of Baltimore; secretary and treasurer, Dr. H. H. Maule. Dr. James Douglas, of New York, and Dr. E. J. Maloney, of Wilmington, Del., are additional directors. The institute has been formed for the purpose of procuring a sufficient amount of radium to conduct extensive experiments in radium therapy, particularly in reference to cancer. Investigations will also be conducted regarding the physical characteristics and chemical effects of radium rays, with the hope that possibly the effects of the rays may be produced by physical means. Ample hospital facilities have already been secured for the experiments.

Supervisor of Public Health Exhibits Wanted.—Among the positions for which the New York State Civil Service Commission will hold examinations on November 25, 1913, is one for the position of supervisor of exhibitions, State Department of Health, with a salary of $1,800 to $2,400 a year. The department is desirous of securing a man between the ages of thirty and thirty-five years, capable of designing and preparing health exhibits, and with experience in the method of holding health exhibitions, and in organizing health campaigns. A knowledge of illustration or design is necessary for the artistic and forceful presentation of material in exhibit form. Subjects of examination and relative weights: Written examination relating to the duties of the position, education, experience, and personal qualifications, 1. The written examination will consist of the writing of a paper, or discussion of some topic, connected with the preparation of a health exhibit.

Philadelphia Joint Lecture Course.—The work of the Rush Society for the Correlation and Support of Medical and Biological Lectures in Philadelphia during the past year has shown that some attempt should be made to develop all lectures on medical and biological subjects in Philadelphia, and to arrange the programme in advance. The Rush Society has therefore entered into an agreement with the committees controlling the Mutter Lecture and the Weir Mitchell Lectures at the College of Physicians of Philadelphia, the lectures of the Philadelphia Pathological Society, and the two lectures supported by undergraduate organizations at the University of Pennsylvania. In another year it is hoped that as a result of previous efforts to combine all such lectures in Philadelphia, and to arrange the programme in advance. The Rush Society has therefore entered into an agreement with the committees controlling the Mutter Lecture and the Weir Mitchell Lectures at the College of Physicians of Philadelphia, the lectures of the Philadelphia Pathological Society, and the two lectures supported by undergraduate organizations at the University of Pennsylvania.
Sugar Content of the Blood under Normal and Pathological Conditions.—Bela Purjesz finds from his investigations that the sugar content of the blood fluctuates considerably within normal limits in healthy individuals. Slight fluctuations are found in the same individual whose blood is examined at intervals of from two to four days, although living on the same diet and under the same conditions. The greater part of the sugar content of the blood is normally in the blood plasma, and only to a less extent in the blood corpuscles; during a rise of temperature the sugar content of the blood corpuscles increases. When the functional activity of the thyroid gland is increased, the sugar content is lowered; it is increased after the subcutaneous injection of the infundibular portion of the pituitary gland in healthy persons. In Addison's disease the demonstrable quantity of sugar is small. Hypertony and hyperglycemia run parallel. During the fever of pneumonia, especially in bad cases, hyperglycemia is present, but in military tuberculosis and in typhoid fever an absolute hyperglycemia was not demonstrable.

Electric Accidents.—Fritz Fischl reports the case of a man, twenty-seven years old, who short circuited a current of 5,000 volts, which passed from one hand to the other. He fell unconscious and was carried to the hospital. Consciousness returned after about half an hour, when he complained of headache and photophobia, even when his eyes were shut. He was weak, depressed, and sleepy, and showed some signs of paralysis, but these symptoms all passed off in a few days. The burn on his hand was slight.

The Power of Resistance of Local Foci of Spirochetes to the Combined Treatment of Syphilis.—Fritz Fischl reports three cases in which he was able to demonstrate the presence of nests of spirochetes in patients who had undergone treatment with neosalvarsan and mercury.

A Mucous Cyst of the Nasal Septum with Postoperative Nasal Hydrorhea.—Victor Fruehwald reports the case of a man, twenty-eight years of age, from whom a cyst containing mucus was removed from his nasal septum. The operation was followed by a profuse discharge of fluid from the nose, which was determined to be cerebrospinal fluid.

Radium and Mesothorium in the Treatment of Malignant Tumors.—Otto Schindler describes at considerable length the details of his experiences in the use of radium and mesothorium rays in the treatment of cancer, and concludes that it is well to employ them prior to operation in all operable and inoperable cancers of the skin, and then if they fail to operate. In all other operable carcinomatas a thorough extirpation should be performed first, and then the field of operation may be irradiated. In some operable cases in which immediate operation is not imperative, or the general condition of the patient contraindicates intervention, irradiation may sometimes be performed successfully. In inoperable cases, without disseminated metastases, an attempt may be made to render the tumor operable by the most intense irradiation, perhaps in combination with other procedures, such as injections of thorium x, and even when metastases have formed, the sufferings of the patient may be relieved by these rays.

Early Diagnosis of Carcinoma of the Stomach.—F. Leitner says that the Röhmer-Grafe test for the early diagnosis of carcinoma of the stomach is not reliable, as it contains serious sources of error.

Radium and Its Therapeutic Use in Dermatology.—Gustav Riehl and Max Schramek describe in a long paper the way in which they are accustomed to use radium, and conclude with a tabulation of their cases, which number in all 245. Of these, 104 patients are still under treatment, sixty-five are apparently cured, seventy-three improved, four unimproved or harmed by the treatment.

Statistics of the Geographical Distribution of Cancer.—Siegfried Rosenfeld emphasizes the need of a careful investigation of areas in which cancer is particularly prevalent, forming "cancer islands" surrounded by land in which cancer is scarce, as well as of the portion of the country in which cancer does not abound, and the comparison of data thus obtained. He states that cancer is apt to abound in old houses, the cheaper rents of which attract the sick with their increasing poverty. He thinks that the supposed rarity of cancer in the tropics is not a fact, but the result of imperfect statistics. In support of this position he quotes figures obtained from various parts of the world. His figures would seem to show that the mortality from cancer is unusually high in Joachimsthal, the region from which we obtain most of our radium. The entire article is well worth reading.

Nonproteinogenous Allergy.—Robert Hift says that he has been able to so sensitize the organism with a chemically simple, colloidal silver preparation, that after a number of injections, or at a certain interval after one injection, a local reaction takes place in circumscribed places in the skin to a reinjection. This cannot be ascribed to accumulative effect, so he thinks it must be ascribed to an allergy, at least of the skin.

Two Successful Operations for the Removal of Bullets from the Vicinity of the Gasserian Ganglion.—Peter Ritter von Walzel reports two cases in which revolver shots lodged in the skull and were located with the x rays. Life did not seem to be endangered, but the symptoms caused were so annoying as to force the patients to seek surgical relief.

Inhibitory Functional Disturbances Associated with Organic Lesions.—M. Klippel and M. P. Weil report the case of a man, fifty-three years of age, who, after slipping on an orange peel, striking the external surfaces of the left shoulder, arm, and
face, but not losing consciousness, developed complete monoplegia of that limb, with anesthesia of part of the hand and loss of tendon reflexes, followed by muscular atrophy. The patient was syphilitic, and showed coldness and cyanosis of the upper limbs, especially that of the affected side, when standing up. In spite of the signs suggesting total neuritis of the brachial plexus, gradual and almost complete recovery followed electric treatment. This leads the authors to aver that in certain susceptible individuals there may readily become superadded to mild nervous lesions marked functional disturbances due in reality to inhibition or concussion. Such disorders must be carefully distinguished both from the serious organic lesions they simulate and from traumatic hysteria, neither the symptoms nor course of which are similar to theirs.

Precautions to Be Taken in Neural Surgery.—T. de Martel insists upon the advantages, in operations upon the nervous system, of having the operating room warmed to 37° C. of dealing with the nervous tissues as gently as possible, of irrigations with tepid saline solution to prevent drying, and of interrupting the operative procedures whenever the blood pressure begins to fall, resuming them only when it has returned to normal. In prolonged operations he has discarded chloroform as anesthetic, uses ether only occasionally, and much prefers nitrous oxide-oxygen under pressure, according to Paul Bert's method.

PRESSE MÉDICALE.
October 4, 1912.

Adrenal Syndromes.—Léon Bernàrd discusses the normal and pathological histology of the adrenals and the symptoms and signs to which disease of these organs may give rise. He divides the clinical manifestations of adrenal disorder into three groups, viz., hypercinephry, hypoeinephry, and the melanodermic syndrome, the first involving the production of high vascular tension, aortic atieroma, and glycosuria; the second, muscular asthenia, low blood pressure, and digestive and nervous disturbances, including mydriasis, delirium, convulsive states, and coma; and the third, pigmentation of the skin and mucous membranes, frequently with epigastric and lumbar pains, and ultimately with hypoeinephry as a superimposed condition. The melanodermic state may appear not only from a partial or even a trifling adrenal lesion but from disease of the solar plexus; it can be controlled or even cured, however, by adrenal organotherapy. It should be borne in mind that tuberculosis of the adrenals may at times induce acute symptoms of hypoeinephry instead of Addison's disease.

SEMÉE MEDICALE.
October 2, 1912.

Diagnosis of Pericardial Effusion and Puncture of the Pericardium from the Epigastrum.—A. B. Marfan asserts that, if a positive diagnosis of pericardial effusions is to be made, the enlargement of the area of cardiac dulness must be accompanied by one of the four following pathognomonic signs: 1. Distinct prolongation of the dull area below the point of cardiac impulse; 2. observation under the x rays of a pericardial shadow with stational margins, and within it of a darker, pulsating shadow representing the heart; 3. dyspnée which compels the patient to bend the trunk forward or assume the knee-chest posture; and, 4. disappearance of the signs suggesting pleurisy over the base of the left lung when the patient is required to assume the knee-chest posture (Pin's sign). Each of these signs, however, is often lacking, and the author advocates puncture of the pericardium as both a diagnostic and therapeutic measure. He much prefers puncture through the epigastrum to either of the other routes hitherto employed. Epigastric puncture has thus far been done twenty-six times in eight patients, with good results and no untoward consequences. With the patient in a semi-sitting posture, the trocar is inserted immediately below the xiphoid and exactly in the median line. It is directed at first upward and backward, then carried up vertically so as to follow the posterior surfaces of the xiphoid and sternum as closely as possible. In children less than five years of age the depth of penetration is about four centimetres and in adults approximately six centimetres. The needle enters the pericardium at the best point for the evacuation of fluid, and passes through neither the peritoneum nor the muscular fibres of the diaphragm. Wounding of the mammary vessels and pleura is avoided, and experience has shown that the heart itself is in no danger. The procedure is advocated for facilitating the circulation and relieving dyspnée in the presence of effusion. Studies on the cadaver have shown it to be contraindicated in marked tympanites and in funnel breast.

BRITISH MEDICAL JOURNAL.
October 18, 1912.

The Investigation of the Higher Nervous Functions.—I. Pavlov has approached this work upon a purely physiological basis, discarding the methods of the psychologist as being inadequate to the conditions. Utilizing some of his previous observations upon the functions of the salivary glands, he has sought to examine the mechanism of the development of reflex actions. He finds that the nervous system has, in addition to the primitive function of reproducing innate reflexes, the capacity of forming new reflexes. He has found it possible to develop entirely new reflexes in dogs by making use of normal strong stimuli. Thus, if a dog is frequently subjected to a painful electrical stimulus applied to a given area of the skin just at the time when he is being fed a reflex to this electrical stimulus will soon develop which is precisely like that shown in response to the exhibition of food. This new reflex is termed a "conditional" reflex in contrast with the normal, or unconditional reflexes. Pavlov explains this on the ground that, "the nervous impulse resulting from the stimulus, which formerly went to a particular region of the nervous system, is now directed to a different one." He says: "In this way we have been able to divert the impulse from one path to another, according to the conditions, and we cannot avoid the conclusion that this represents one of the most important functions of the highest parts of the central nervous system." The relative functional power of the several centres, or their de-
gree of irritability, seem to be the factors which determine the direction of the nervous impulse along certain special channels. It is easy to produce conditional reflexes in connection with feeding, for the feeding reflex is prepotent as compared with many other reflex responses to stimuli. One or more of the many adventitious stimuli which arise in connection with the performance of an experiment may readily become a conditional reflex. These adventitious stimuli may constitute a decided obstacle to the formation of the desired conditional reflex by creating a focus in some particular region of the cerebrum, resulting, in turn, in a relative depression of the excitability of the other brain centres. In the presence of this lowered excitability the desired stimulus falls below the threshold value of the centre concerned, or is blocked from passage to other portions of the brain. These newly developed conditional reflexes are readily subject to inhibition by many factors. There may be a spontaneous inhibition through the development of a drowsy condition of the animal. Inhibition may result from the entrance of other stimuli, coming from without. By altering the time relation between the conditional stimulus and the unconditional one, or by omitting the unconditional one for a few times, an internal inhibition may arise. A "conditional" inhibition may appear if the conditional stimulus is accompanied by an indifferent stimulus. As the result of extirpation of the entire cerebrum no conditional reflexes can be formed, leading to the conclusion that the cerebrum is the organ by which sensations are analyzed and new reflexes are built up: "It is an organ for direct and appropriate adjustment to the most varied combinations and changes in the phenomena of the surroundings; it is the organ which is above all others necessary for the unimpeded evolution of the organism. It is perhaps not rash to think that some of the newly formed conditional reflexes can be transmitted hereditarily and become unconditional thereby."

"Struma," an Important Factor in Disease of the Eyes.—T. Harrison Butler believes that chronic, nonviral tuberculosis is the causative factor in a large number of affections of the eyes. He bases his belief on the frequency with which the subcutaneous injection of tuberculin gives a focal reaction in the suspected eye, and on the striking curative powers of small doses of tuberculin in many eye conditions. Among the affections which are often due to tuberculosis of a chronic type are: Phlyctenular ophthalmitis, in which it is the commonest cause; photophobia in children; scleritis; interstitial keratitis, in thirty per cent. of the cases; iritis; cicatriz; and choroiditis.

On the Rigidity of Calcified Arteries.—A. H. MacCordick's attention was drawn to the fact that during life arteries of stony hardness are very seldom encountered, while post mortem they are often found. Even in cases of senile gangrene of an extremity the vessels are usually sufficiently soft to permit of occlusion by ligature, yet the same vessels are brittle and tend to break after the part has been amputated. From experimenting with specimens of such arteries, removed very shortly after death or at operation, and from experiments with mixtures of calcium oxide and calcium phosphate subjected to various chemical conditions, MacCordick concludes that the alkaline reaction of the tissues in life is the cause of the pliability of calcified vessels. Very shortly after the death of the tissues their reaction becomes acid, and this change leads to the setting of the calcium deposit present.

Significance of the Wassermann Reaction in Gynecological Diagnosis.—A. Louise McIlroy and her collaborators have carried out this test in a series of 100 unselected cases. Although most of the cases gave no history or symptoms which would suggest syphilis, the reaction was positive in thirty per cent. Especially worthy of note is the fact that it was positive in a very large proportion of cases of uterine hemorrhage and such patients recovered rapidly under specific treatment.

Circulatory Disorders in Relation to Alopecia Areata.—David Walsh suggests that some circulatory disorder is at the bottom of most cases of alopecia. His hypothesis is that the tissues under normal circulatory conditions are able to resist the inroads of the cutaneous bacteria, while, when the circulation is deficient, this resistance is diminished, permitting the bacteria to gain a foothold. The organisms cause an inflammatory reaction about the bases of the hair follicles, the circulation in the capillaries is cut off, depriving the follicles of nutrition, and causing the hair to fall out. Recovery from the infection leaves a cicatrinal deposit, which, if sufficient, renders the baldness permanent. The predisposing condition is a circulatory disorder, the exciting cause a traumatism, usually bacterial in origin. Treatment should take the circulatory disturbance into consideration. On the other hand, baldness is so often associated with some circulatory deficiency that its presence should always lead one to suspect some disturbance in the circulation.

Some Applications of Antenatal Eugenics in Heredity.—D. Berry Hart succinctly presents the salient points in heredity as brought out by the work of Darwin, Mendel, and Weismann and their followers, and holds that the points which have an important bearing upon antenatal eugenics are: 1. The continuity of the germ plasma. 2. The origin of the hereditary cells, not from the somatic cells covering the sex gland, but from an early division of the zygote. 3. The distributed and transmitted determinants of qualities giving rise to variation by means of the mitoses in the hereditary cells and their maturation prior to fertilization, these processes being carried out according to the law of probability. 4. Natural selection considered as an eliminant. 5. The antonym of the unit characters, and therefore the autonomy of the causal zygotic determinants. 6. The probability result of the distribution of the determinants in the zygotes by which each of the contrasted characters has a twenty-five per cent. chance of its pure distribution." He believes that the important antenatal changes in the hereditary cells before fertilization are intrinsic in the germ plasma, and are hence beyond any direct control. From this it is evident that we
must look to postnatal eugenics for much valuable progress. The abnormal human conditions which are due to germ plasma conditions and distributions fall into two groups. In the first are “those inherent in the germ plasma determinants and subject to ordinary variations and distribution.” Such are the neurotic strain, minor and major degeneracies, etc. The second group is made up of “those that are due to loss of determinants at maturation and are therefore characterized sometimes by a striking manifestation of deformity.” In de Vries’s sense they are mutations. These are of two classes—those limited to one sex, such as hemophilia and brachydactyly, and those found in both sexes, as achondroplasia. In the application of the known facts of heredity it is obvious that legislation will not be of much avail, but, like all great social advances, success is to be attained chiefly through the education of the people.

**Relief of the Pain of Laryngeal Tuberculosis.**

—Edward D. Davis advocates the resort to one or more of the usual methods; but, in addition, finds the injection of alcohol into the internal laryngeal nerves of especial value in lesions of the ventricular bands, anterior surfaces of the arytenoids, aryteno-epiglottic folds, or of the laryngeal surface of the epiglottis. The larynx is pressed toward the side which is to be injected; the nerve is indicated by the nail of the index finger, placed between the hyoid bone and the thyroid cartilage immediately above the superior thyroid tubercle, at a spot that is usually found to be tender; over the centre of the nail the blunt needle of a Sloscher syringe is inserted to a depth of 1.5 cm. By carefully moving the needle a spot is found at which the patient experiences pain in the ear. At this point one or two c. c. of the warmed alcohol is injected. Davis uses a solution of two grains of eucaine in an ounce of eighty per cent alcohol. In twelve cases he has had only two in which there was failure to secure relief.

**Hereditary Optic Neuritis.**—A. S. Worton contributes an account of eleven cases of this rare disease, all of which occurred in males in three generations. In each case the disease was transmitted through an unaffected female. The cases were all descended from a common pair of ancestors, neither of whom was affected. In the series the ages ranged from nine to thirty-two years. Four patients were examined by the author, and two of those have gained nearly normal vision, having only some deficiency in light sense.

**Treatment of Infections by Means of Fixation Abscesses.**—De Los talot is a strong advocate of this procedure in such conditions as puerperal sepsis, infectious arthritis, pneumonia, appendicitis, typhoid fever, etc. He acknowledges that the method is empirical, the precise mode of action not being understood as yet. Nevertheless, de Los talot’s experience of it has been such as to lead him to say: “It is of the greatest importance that time should not be lost in trying other methods before employing this; it is far better to form a ‘fixation abscess,’ and then the other methods can be used as well.” The method is simple, consisting in injecting aseptically two c. c. of pure oil of turpen-

tine under the skin of the gluteal region. An immediate sharp pain results, which may be relieved by the application of a hot fomentation. In three or four days a sterile abscess has formed. This is incised, but must not be allowed to drain, and a Bier’s cup is applied twice daily. Healing will be complete at the end of a week and “the patient will be cured.”

*September, 1913.*

**Hereditary Dupuytren’s Contracture.**—J. L. Bunch relates a case of Dupuytren’s contracture which he had observed in a father, his son, and his grandson; and which disease, according to their statements, had affected the male members of their family for the last 300 years. It is only the male members that transmit the disease and the male members alone are affected. The disease started at about the same age, reached its height about the same time, and the same finger was involved in each instance. The author has been unable to discover any case of inherited or hereditary disease which would parallel the case under consideration.

**INDIAN MEDICAL GAZETTE.**

*September, 1913.*

**Iodine as an Aid to Aseptic Vaccination.**—E. E. Waters pictures the dirty arms to be seen in India (sometimes elsewhere), and has obtained most satisfactory results from the following practice: The arm is painted with tincture of iodine, and at the same time the vaccinator, as he holds the arm, paints his left thumb nail. The lancet blade is dipped in the tincture and allowed to dry. A sufficient quantity of lymph is extracted from the tube with the now sterile knife and placed either directly on the iodined arm, or on the left thumb nail, vaccination is then performed through the iodined skin and no dressing is applied.

**BOSTON MEDICAL AND SURGICAL JOURNAL.**

*October 23, 1913.*

**An Anatomical and Surgical Study of Pericelcal Membranes.**—Michael E. Fallon concludes that the so called “Jackson membrane” is a congenital, normal, peritoneal membrane, and is not a membranous pericelitis. It may be confused with the pericelitis of Virchow. The ascending mesocolon is a less frequent form of attachment of the ascending colon; the accompanying cæcum mobile in itself is not pathological. Digestion in man requires the retarding of the food current in the first half of the large intestine—the physiological stasis. When this stasis is pathological the causes frequently are faulty habits, and hygienic and dietary, rather than surgical measures, as a rule, are indicated. Pericelcal membranes frequently predispose to appendicitis, and afford one explanation for family appendicitis.

**Some Newer Methods of Reducing the Mortality of Operations on the Pelvic Organs, by G. W. Crile.—See this JOURNAL for June 28th, p. 1366.**
Can Rabbits Be Infected with Syphilis Directly by the Blood of General Paretics? by W. W. Graves.—See this Journal for July 5th, p. 47.

Clinical Report of Seven Cases of Hydrophobia, Together with a Case Clinically Similar, with Recovery Following Injections of Quinine.—D. L. Harris reports these cases. The seven cases referred to all ended fatally. In the case which recovered ninety grains of quinine and urea hydrochloride (in fifteen grain doses) were administered intravenously in twenty-four hours. In commenting on this case the author says that the fact of recovery raises the question of diagnosis, which rests solely on the clinical history. There were certain elements, however, which made for exclusion of hysterical fear of the disease. The patient had been bitten many times before by dogs, and he did not consider the last bite of sufficient importance to seek medical attention. It had altogether escaped his mind until the pain began. All the clinical manifestations were of such a character as seemed to warrant the diagnosis of rabies.

Holding Fractures with Absorbable Material—Ivory Plates and Screws.—P. B. Magnusos ascribes the following advantages to ivory: 1. Ivory is absorbed when in close contact with living healthy tissue. 2. It does not loosen, like other materials, when inserted in bones. 3. It does not produce necrosis or softening in the bone in contact with it. 4. In oblique fractures but little manipulation is required in the use of ivory screws; the screws maintain a strong hold on the fragments; there is no irritation, and there is nothing to take out after the fracture has healed. 5. In transverse fractures ivory plates fit closely into the fragments, do not loosen up, are strong enough to withstand any pull by the muscles attached to the fragments, will not allow angulation, especially if put in at right angles to the greatest tendency of displacement or, better, to the greatest pull of the muscles, will be gradually absorbed, and never act as a foreign body in the bone.

Bacterial Invasion of Blood and Cerebrospinal Fluid by Way of Lymph Nodes: Findings in Lymph Nodes Draining the Pelvis.—E. E. Southard and M. M. Canavan give the following summary of their study: 1. This continuation of former work shows that the cerebrospinal fluid (seventy-two per cent.) still leads the heart’s blood (sixty-eight per cent.) in the proportion of positive cultures (routine aerobic methods; post mortem material). 2. Pelvic lymph nodes lead both blood and cerebrospinal fluid (seventy-five per cent.). 3. This is possibly due to the great proportion of pelvic lesions in the present series. 4. It is still uncertain whether these findings indicate ante mortem or post mortem invasions. 5. If, as seems likely, the invasions are intravital or intestinal, it would appear that the pelvic lymph nodes are accustomed to harboring many bacteria. 6. Whether this habit of receiving more organisms than other nodes induces any superiority on their part in respect to power of digestion is unknown. If so, a rationale for Fowler’s drainage position might be imagined. 7. The pelvis, often subject to acute and chronic disease in the insane, appears to supply its lymph nodes with very numerous bacteria. Some of these are saprophytes, some doubtless pathogens; they are often found in the cerebrospinal fluid post mortem, even when absent (destroyed?) in the blood.

A Discussion of Various Anesthetics and Methods. Experimental Observations.—B. F. McGrath says that the best anesthetic administered by the most expert anesthetist would be the ideal in anesthesia; but such an ideal condition is no more feasible than that every surgical operation be performed with the best technic by the most skilful surgeon. No other anesthetic or method for application in general is so soundly supported by time and experience as that administered by an expert, with a due allowance of air to the patient, and, compared with other anesthetics and methods, either by the so called drop method is at least as immediately and is more available, more economical, and more conducive to efficiency in extensive work. This is the position of the Mayo Clinic on the question of general anesthesia, as shown by the statistics from 1900 to 1913. After referring to the preliminary administration of drugs, such as scopolamine, atropine, and morphine, the author states that the present tendency at the clinic is toward simplifying the employment of local anesthetics. He then reports that for three months he has been pursuing experimental investigations on the subject of general anesthesia, but does not deem it advisable to discuss the results of these at the present time. One hundred and fifty-three experiments have thus far been undertaken on 145 dogs, and the anesthetics employed were ether, chloroform, paraldehyde, paraldehyde and ether in combination, urethane, and nitrous oxide-oxygen-ether.

MEDICAL RECORD.

October 25, 1913.

A Case of Pseudobulbar Paralysis Presenting Spastic Movements Simulating Laughter.—B. Oettinger reports this case, and in connection with it refers to cases of similar character seen by other observers and tabulates twelve cases of spastic laughing and eighteen cases of spastic crying. He discusses the terminology, classification of cases, and pathology, and states that his study demonstrates our need to note the conditions which relate to subcortical lesions. Here localization refers to nerve tracts, of projection and association, and, in case subcortical gray masses be involved as the added factor, reflex centres inherent to these ganglia. Hence modification of cortical impulses upon basal gray masses may be as effectively brought about by tract interruption or irritation as by lesions of ganglia themselves in which central neurons are rearranged or through which cortical projection fibres pass. For this reason, for instance, frequency of lenticular disease in the face of evidence that such lesions are vital to forced movements of laughing and crying fails to negative a like effect from softening of supranuclear tracts communicating with this ganglion.

Mild Manifestations of Syringomyelia, with Report of Three Cases.—C. B. Craig comments on the increasing number of reported cases of syringomyelia in American literature as bearing noteworthy testimony to the more widespread knowledge possessed by the general practitioner.
and to his greater care in examining cases. In regard to the three cases which he reports in detail he says that they show a great disparity between the motor inconvenience experienced by the patient and the unsuspected sensory disturbance. The mild degree of atrophy and other trophic disturbance and the comparatively slight loss of motor power indicate the remarkable manner in which the depredation of the spinal glosis is confined, in the early stages at least, to the sensory tracts bearing thernic and pain sensations, tactile and postural sense being unimpaired. The symmetry of the sensory disturbance is worthy of note as favoring the belief that the Anlage of the disease is of congenital origin, consisting of an inclusion of the glial cells in the posterior median fissure of the spinal cord during the involution of the neural ectoderm.

The Röntgen Rays in the Diagnosis of Diseases of the Stomach.—I. H. Levy says that the x rays give us a definite idea of the shape, location, and size of the stomach. They show the depth, rapidity, and direction of the peristaltic waves, and enable us to determine the motor power of the organ, and also by the aid of variously coated bismuth capsules of different weight the amount and character of the secretions. It cannot be too strongly emphasized, however, that the rays are not to be invoked as a first aid. Alone, they do not make the diagnosis; they are simply a diagnostic aid, and should be employed only in conjunction with all other aids. The Röntgen rays, whether we use the fluoroscope or radiograph, give us only a picture, and it is the interpretation of this which is all important. The x ray examination must be checked up and controlled by all other methods, and if it contradicts the other findings great care must be used in coming to a conclusion. As to its assistance in the diagnosis of gastric ulcer, the latter-day is that in simple ulcer the bismuth does not help us to locate the lesion. But in cases of chronic ulcer of the pylorus leading to stenosis the diagnosis by means of the x ray is very simple, and in another form of ulcer, the "ulcus penetrans callosum" of Haudek, it makes a positive diagnosis. In fact, this is the only means of making a diagnosis previous to operation. The hour glass type of stomach also can be diagnosed with certainty only by this means: When the stomach is adherent to surrounding organs or structures the adhesions cannot be seen with the x rays; yet we are able by this means to suspect their presence. Cancer of the stomach in its incipient cannot be diagnosed, but when a tumor is present which encroaches on the lumen of the organ, by means of the x rays we can see the destructive shadow. This can often be discerned before the mass is palpable; which is already a great gain. But we can frequently suspect cancer even before there is a break in the bismuth shadow, and, in fact, the Röntgen picture may take the place of an exploratory incision. Although, unfortunately, the x rays as yet do not make the early diagnosis possible, the author believes it may safely be asserted that if all cases were seen early enough and x rayed, the prognosis of the surgical treatment of gastric cancer would be much better.

The Frequency of Amentia as Related to Sex.—Miss L. S. Hollingworth, of the Clearing House for Mental Defectives, New York city, states that more males than females are brought to the Clearing house in a ratio of about 1.3 to 1.0. Between the ages of two and sixteen years there is a very marked preponderance of males, but above sixteen, a marked preponderance of females.

American Medicine.

September, 1913.

The Need for Coordination of Antituberculosis Measures.—Sir R. W. Philip says that tuberculosis is an insidious infection which, although readily prevented and treated when appropriate means are used for a sufficient length of time, is yet tenacious and illusive to a high degree. The recognition of these features must be the prelude to any sound programme of prevention and treatment. It is because tuberculosis is so insidious, so tenacious, and so illusive, that more specialized procedure has to be adopted than is needed for other fevers. The time has come when the disease in its remarkably varying expressions, must be handled as a definite entity. It is extensive enough, with its complex issues, to warrant the starting of a special department of public health activity. What is needed is an organized and coordinated scheme which will include and link together the different institutions and agencies which the circumstances require. The essential unity underlying the endless diversity of expression of this disease calls urgently for centralization of intelligence and direction, and the remarkable diversity of manifestations affords the reason why differentiation is necessary in the provision of institutions for its treatment. The experience of thirty years has convinced the author that it is only by intimate correlation and careful coordination of the several factors that satisfactory and permanent progress will be made in the struggle with tuberculosis.

Intravenous Injections of Neosalvarsan in Septic Scarlet Fever.—Louis Fischer states that he has employed this treatment in fifteen cases, but feels that a larger number must be treated before its merits can be passed upon. One fortunate point stands out prominently in its commendation—that he has not seen one deleterious symptom follow the use of neosalvarsan. When high fever existed a decided and striking antipyretic effect was noted within from twenty-four to forty-eight hours after one injection, and this was observed in twelve of the fifteen cases. The injection was usually given when the disease appeared to be at a standpoint, with a decided loss of resistance. While there was no immediate amelioration of the symptoms, the neosalvarsan seemed to provide an increased power of resistance by elevating the general tonicity of the system. He believes there is some virtue in the drug and that it merits a more extensive trial, since it benefited some of the patients whose cases he reports.

The High Frequency Current as a Rational Treatment in Tic Douloureux.—A. C. Gysler maintains that from the conditions associated with tic douloureux, and the special qualifications char-
acteristic of the high frequency current, from a theoretical point of view at least this current is the most logical and scientific therapeutic agent that could be devised. The practical results, he says, are most gratifying. During his earlier cases his patients had complete relief and recoveries in sixty-five per cent. of the cases, while by properly selecting suitable cases, with wider experience and improved technic, he is now able to promise satisfactory results to eighty per cent. of his patients.

ARCHIVES OF INTERNAL MEDICINE.
September, 1913.

Nitrogen Retention and Phenolsulphonphthalein Excretion.—C. Frothingham, Jr., R. Fitz, O. Folin, and W. Denis report experiments in which the amount of nonprotein nitrogen, including urea, retained in the blood in rabbits rendered nephritic by uranin, was estimated and compared with the already clinically used phenolsulphonphthalein test for renal function. In general the results obtained from the two procedures were found to parallel each other as indicators of renal capacity, with the difference, however, that whereas the excretion of the drug showed the kidney function at the moment the test was performed, the nitrogen retention represented an accumulating difference between the amount of waste nitrogen produced in metabolism and that eliminated by the kidneys. The previous duration of the nephritis was therefore an important factor in determining the results of the nitrogen test.

Reaction of Salomon and Saxl as a Diagnostic Test for Carcinoma.—Isidore Greenwald found no difference between the urines of patients with carcinoma or other diseases and normal individuals in their response to this test, and concludes that the latter is of no value in the diagnosis of carcinoma.

Protein Metabolism in Pregnancy.—J. R. Mur- lin and H. C. Bailey found that in a normal pregnancy and peripuerium the proportion of ammonia nitrogen in the urine before and after labor lies within the ordinary limits (from four to six per cent.), except for one or two days immediately following delivery, when it is slightly increased (from seven to ten per cent.). High ammonia may, however, be encountered in normal cases because of bladder contamination, and reduced amounts after irrigations of the bladder with boric acid solution. The percentage of total nitrogen eliminated as urea in the last month of pregnancy is somewhat diminished, largely owing to retention of nitrogen for the growth of the fetus. The ammonia nitrogen, on the other hand, may be as high as twelve per cent. and be unaccompanied by any unfavorable symptoms. Since it is subject to marked variations arising through catharsis or changes in diet, the absolute ammonia nitrogen value is much more reliable than the percentage; it varies but slightly from day to day. Any amount up to 0.12 gramme of ammonia nitrogen to the kilogramme of body weight in the twenty-four hour urine is well within normal limits. The creatinin coefficient is probably increased in pregnancy, creatinin occurs in the urine, and the total purin nitrogen is slightly higher than in normal male subjects on similar diets.

Use of Pituitary Extract in Obstetrics.—F. C. Harrison deems pituitary extract of great value in cases of weakness in uterine contractions after the soft parts are well dilated. The later in labor, but before delivery, the more striking the effect. As an addition to some mechanical method, e. g., the Champetier de Ribes bag, it is of great value in bringing on premature labor or abortion. In the former case it may be sufficient in itself, but there is some risk of tetanus of the cervix or uterus, especially when repeated injections are required. For delivery of the placenta its use is accompanied by the danger of tetanus uteri and retention. In post partum hemorrhage a considerable proportion of failures may be expected.

Intraspinous Injections in the Treatment of Syphilitic Affections of the Central Nervous System.—H. F. Swift and A. W. M. Ellis, in view of the fact that there is very little excretion of curative agents from the blood into the cerebrospinal fluid, were led to study the effect of injections of the serum of salvarsan treated cases into the subarachnoid space of patients with central nervous syphilitic disease. Their technic has already been described (see this Journal for July 13, 1912, p. 53). In the present paper they report gratifying results in an additional series of cases, laying special emphasis on the improvement in the condition of the cerebrospinal fluid as revealed in the number of cells contained, globulin, and Wassermann reaction. Their present treatment is to give 0.45 or 0.50 gramme intravenously every few weeks, and in addition intraspinous injections of thirty cubic centimetres of forty per cent. salvarsan serum. Most of the cases under observation have been of tabes, though some improvement has also been noted in a few paretics. By careful clinical examination, as well as examination of the cerebrospinal fluid, many cases of tabes could probably be detected in an early stage and arrested by intensive and prolonged treatment. Many tabetics give a history of diplopia or other transient eye disturbances several years before the onset of any other symptoms. In the treatment, each case must be considered individually, as some respond much more rapidly than others. In all, however, the object should be to obtain a persistently normal cerebrospinal fluid. Combined intraspinous injections and intensive intravenous treatment is indicated in all cases of rapidly advancing tabes and paresis, or where the disease has resisted other forms of treatment.

INTERSTATE MEDICAL JOURNAL.
September, 1913.

Cerebrospinal Meningitis: Some Atypical Manifestations and a New Diagnostic Aid.—N. P. Barnes says that the result of his observation of this disease as it has occurred in and around the District of Columbia during the past two years is to bring out the atypical character of the cases. The following facts are worthy of mention: 1. Cervical opisthotonos one of the very last signs to develop. 2. The contraction of the recti and other abdominal muscles, noticeable in all the cases. 3. In several instances the symptoms for a week or more could have been mistaken for any other disease, on ac-
count of the absence of the classical symptoms of meningitis. 4. The disproportion between the pulse rate and temperature, particularly noticeable in three of the cases. 5. The dilatation of the pupils produced in all cases when Kernig's sign was being elicited; also in several instances when the head was being flexed upon the chest. 6. The complete covering of the palate with herpes vesicles in two of the cases. 7. The ability to produce the rash in true cerebrospinal meningitis with the electric light and reflector; which phenomenon could not be induced in meningitis of other type. 8. The necessity for prompt examination and reexamination of the spinal fluid. 9. The importance of making a leucocyte count.

The Acute Diarrheas of Infants.—It is possible, says R. M. Smith, to differentiate certain fairly distinct groups, and the recognition of these groups is important because the treatment of each group differs from that of the others. He first describes the group associated with disturbances of digestion and the treatment of the conditions met with. In the second place he takes up the affection popularly known as "summer complaint," the cases of which come in waves, while certain facts would seem to indicate that the cause of disturbance is in some way related to atmospheric conditions. In the third group, infectious diarrheas, bacteria play a primary rôle. These are the dysentery bacillus, the gas bacillus, and other organisms not yet fully determined. The symptoms are digestive and toxic, and diarrhea is usually the first sign of the disease. Treatment consists of two things: Treatment of the toxemia (by far the more important) and treatment of the local condition. A cathartic (preferably castor oil) should be given at first; then water should be given freely, and all food withheld. Normal salt solution, by subcutaneous injection, may be called for. In from twelve to fourteen hours after the initial purgation a five per cent. lactose solution should be given. Milk should be withheld for a considerable time, and it is rarely wise to increase the diet so long as the temperature is elevated or the stools contain blood. Dextrose infusions, 2.5 per cent., may be given as another means of supplying food and liquid. Stimulation is often necessary. In the local treatment cleanliness is most important. Irrigations of the colon with normal salt solution or plain sterile water should be given twice daily, provided they are not followed by a severe depressing reaction. In gas bacillus dysentery, the symptoms of which resemble those of the bacillary type, the treatment consists in the administration of food of high protein and low carbohydrate composition.

The Influence of the Injection of Tuberculin on the Eosinophile Cells in the Peripheral Blood.—J. M. Swan gives the details of the differential leucocyte counts in eight cases in which tuberculin injections were made for diagnostic purposes, in order to determine, if possible, the influence of tuberculin on the eosinophile leucocytes. In these cases eosinophilia was seen after the injection of the tuberculin in five instances and was absent in three. In the latter cases the reaction was negative. From these results two conclusions might be drawn: First, that eosinophilia is due to the fever accompanying a positive reaction; second, that after the injection of five milligrammes of tuberculin in a person who is not suffering from tuberculous infection, not enough tuberculin is administered to produce the eosinophilia. The first conclusion must be rejected, because all elevations of temperature are not accompanied by eosinophilia. The second conclusion may or may not be justified, though the author has no evidence to offer on this point.

JOURNAL OF CUTANEOUS DISEASES.

Additional Studies on the Presence of Spirochaeta Pallida in General Paralysis and Tabes Dorsalis.—H. Noguchi's article may be divided into two parts for the purpose of analysis. First, a historical résumé of the etiology of general paralysis and tabes. It is admitted by the majority of clinicians that tabes and general paralysis are in their origins intimately connected with a previous luetic infection. This statement has met with a great deal of opposition, owing to the fact that neither of the above mentioned diseases show the characteristic pathological changes of lues, and they are neither cured by the remedies that have a curative influence in syphilis. On the other hand cerebro- and cerebrospinal lues show the characteristic pathology of lues and yield to antisyphilitic medication. It is because of these facts that general paralysis and tabes have been called parasyp bilateral, metaleutic or postluetic conditions, and it is also true that some authors have advanced the theory that tabes and general paralysis are the result of some toxic substances emanating from some as yet unknown metabolic analogy brought about by a previous luetic infection; and it is because we have to deal with the aftereffects of the disease that the syphilitic remedies prove unavailing. Secondly, concerning the technic and technical difficulties of finding the spirochete in general paralysis and tabes, the author states that he was led to the study of this problem, by the observation that at times and under certain conditions in pure culture, the spirochete assumed the form of minute granules, from which, upon transplantation into suitable media, spiral forms were seen to sprout. This suggested the thought that possibly the spirochete assumed the granular form in cases of parasyphilis. For this communication the author has examined the brains of 200 cases of general paralysis, and was successful in finding the spirochete forty-eight times. He also examined the spinal cords of twelve cases of tabes; spirochetes were found in only one case. In the cord the difficulties are greater than in the brain, because in cutting the sections transversely, the search for spirochete is hampered by the pressure of numerous neuroglial fibres and cross-sections of nerves; but by cutting the sections longitudinally, this difficulty was minimized. The spirochetes were found more abundantly in the cortical layers. Noguchi emphasises certain points in technic: First, it is often advisable to cut sections of five millimetres thickness instead of two millimetres, as it is easier to identify the spirochete in the interior postures. Second, that neuroglia fibrils stain well in an imperfectly fixed tissue, and the spiro-
chete never takes on the silver impregnation, unless the tissue be completely fixed prior to impregnation. Third, that prolonged formalin fixation interferes with the staining of neuroglia and accelerates the staining of spirochete. The nerve tissue (brain or cord) of five to seven millimetres thickness is placed in a mixture of ten per cent. formalin; ten per cent. pyridin; twenty-five per cent. acetone; twenty-five per cent. alcohol, and thirty per cent. distilled water for a period of five days, at room temperature. The tissue is then washed in distilled water for twenty-four hours. Next put in ninety-six per cent. alcohol for three days and thoroughly wash in distilled water for twenty-four hours. After this the following directions are carried out in a dark bottle. Bat in 1.5 per cent. nitrate of silver solution for three days at 37°C. (or five days at room temperature). Wash in distilled water for several hours. Reduce in a four per cent. pyrogallic solution with the addition of five per cent. formalin for twenty-four hours at room temperature. Wash in distilled water. Transfer to eighty per cent. alcohol for twenty-four hours. Then ninety-five per cent. alcohol for three days. Absolute alcohol for two days. Xylol, xylol paraffin, and paraffin. When the staining is successful the various tissues of the brain appear in color varying from pale yellow to yellowish brown, while the pallids are pure black.

JOURNAL OF INFECTIOUS DISEASES.
September, 1913.

The Toxicity of Human Tonsils.—At present various investigators are asserting that there is a definite relationship between the tonsils and asthma. One man considers the possibility of these cases being due to the absorption of toxic substances from the tonsils. Dick and Burmeister undertook to determine by their experiments just whether or not there are toxic substances in the tonsils; second, if present, the nature of those substances; and, third, the factors influencing the degree of toxicity. Extracts of the tonsils, removed at operation, were made by grinding them in a mortar with salt solution. The extract thus obtained was either centrifuged or filtered through paper. On injecting rabbits and guineapigs with this substance the animals died in a few minutes with symptoms closely resembling those of anaphylactic shock. The post mortem examinations also showed the changes found in these conditions. The authors conclude that extracts of tonsils are acutely toxic for animals. That these substances affect animals in a manner similar to that of anaphylatoxine. The results of their work also would indicate that as a rule extracts of those tonsils which are associated with hemolytic streptococci are most toxic.

Studies on the Cultivation of the Virus of Vaccinia.—Steinhardt, Israeli, and Lambert undertook a series of experiments to determine whether or not the virus of vaccinia could be caused to increase by being grown artificially. They took small pieces of rabbit or guineapig cornea and placed them for a few minutes in a weak elusion of virus. These pieces were then transferred with a small quantity of the virus to cover glasses to which drops of rabbit or guineapig plasma were added. These were then incubated and at the end of from seven to eighteen days were rubbed on the freshly shaven skin of a rabbit. In every instance an extensive confluent eruption occurred, while with unincubated specimens discrete vesicles, from ten to fifty, were formed. As a result of the cultivation in vitro of corneal tissue plus the virus of vaccinia the authors state that there is a multiplication of the virus of vaccinia although no specific vaccine bodies are found in the preparations.

The Treatment of Tetanus.—McClintock and Hutchings come to some important conclusions concerning the treatment of tetanus in consequence of their experimental work. They believe that there is little if any value in the carbolic acid treatment of the disease. If there is any gain, it is probably due to the sedative action of the drug and not to any direct action on the disease process. The subcutaneous use of magnesium sulphate also proved of no value. The only thing of value was antitetanic serum, which alone had a definite, but usually insufficient, curative action. The authors, from the observations of a large number of animals and quite a number of human beings dying of tetanus, believe that the exhaustion due to the muscular contractions is a large factor in producing fatal results. According to them the best that can be done in the treatment of tetanus is to neutralize the toxin with repeated doses of serum while controlling the muscular spasm with some such drug as chlorbutanol.

NEW YORK ACADEMY OF MEDICINE.
Section on Pediatrics.

Stated Meeting, Held October 17, 1913.

Dr. Henry D. Chapin in the Chair.

Atypical Infantile Paralysis.—Dr. F. L. Wach-Enheim, of New York, read this paper, in which he called attention to the large proportion of atypical cases in the present epidemic of infantile paralysis which had prevailed since 1907. In the typical or classical form of the disease the patient felt suddenly ill with moderately high fever, more or less marked gastrointestinal disturbance, and general weakness of the extremities. In a few days the fever abated and left the child paralyzed in one or more limbs. This paralysis gradually passed off except for one group of muscles, usually in the lower extremity, which remained atrophied for life. Infantile paralysis was considered a disease of the anterior horns, usually of the lower spinal cord, rarely involving other portions of the gray matter, though the polioencephalitis of Wernicke and that of Strumpfel were regarded as possible variations of the type described.

During the epidemic of last fall the writer observed seven cases in all, only one of which was typical. The other six were so atypical they were worth reporting in detail. In the first case the child had had a temperature up to 106°F. and the prognosis seemed doubtful as to life and poor as to the
restoration of the impaired muscle, yet he made a rapid and complete recovery, save for a slight weakness in the left leg. All of the other cases showed severe cerebral symptoms. A deep somnolence was a characteristic feature of the entire group. Many authors insisted that the cerebral affections associated with poliomyelitis did not affect the cortex but only the basal ganglia, while others did not accept this restriction. The whole matter was far from a final decision but the frequent grave disturbance of the sensorium was strong evidence that the cortex was sometimes involved. A most unusual feature of the third case reported was that of localized facial sweating. General hyperhidrosis in infantile paralysis might very well be attributed to the disturbance of the sweating centre in the medulla oblongata, and was therefore especially likely to occur in cases of the cervical and cerebral types. In the case under consideration it seemed reasonable to bring this local sweating into relation with a slight facial paralysis which was present, though the connection was not as clear as one might wish. The fifth case reported was unusual on account of the prolonged subfebrile temperature with tachycardia lasting seven weeks. This child then succumbed, during an attack of bronchopneumonia, to acute dilatation of the heart. There was no doubt but that in this case the involvement of the gray matter was unusually extensive and it was quite possible that the patient suffered from grave impairment of the cardiac innervation. The last case was apparently one of meningitis but this diagnosis was rejected because of the preponderance of lymphocytes in the cerebrospinal fluid, the absence of meningococci, the rapid recovery from the uncommonly severe symptoms of posterior basic involvement, and the absence of an epidemic of cerebrospinal meningitis at the time. Tuberculous meningitis was excluded by the high leucocyte count, the acute onset, the favorable outcome, and the negative von Pirquet reaction. The other forms of meningitis would have shown their respective germs and would also have ended fatally, and, hence, one was safe in excluding them. The speaker called attention to the series of cases reported by Koplik in which symptoms recalling both cerebrospinal and tuberculous meningitis dominated the clinical picture throughout the course of the disease. While no records could be found of another case presenting, as did this one, optic neuritis terminating in atrophy and amaurosis, such an untoward event was readily conceivable. It is possible that the fulminating lesions of doubtful value in severe cases of meningoencephalitis, seemingly varying according to the intensity of the infection, rather than the etiology of the disease. A characteristic feature of these cases was the acute onset, the high leucocyte count, differing from the findings in ordinary poliomyelitis. The cerebrospinal fluid was at first cloudy but differed from that of cerebrospinal meningitis in that the sediment consisted chiefly of leucocytes; in a few days the fluid cleared up leaving only a delicate fibrin on standing. The germ of poliomyelitis which had only just been identified might be discovered in the spinal fluid of this group. The intraspinal pressure was usually not high, far lower than in the usual forms of meningitis. The temperature was apt to run the course usually observed in poliomyelitis, possibly rather higher at first, but falling to normal before the remission of the grave cerebral symptoms. The most striking feature was the disproportion between the cerebral symptoms and the general condition of the patient; this was the chief guide to the real diagnosis in his case. Such a discrepancy was so remarkable that it could not fail to attract the attention of the attending physician and clear up speedily all doubts as to the type of the disease. The resulting paralyses were apt to be of the flaccid type distinctive of poliomyelitis, not spastic as after ordinary meningitis. The remarkable variations displayed by so small a clinical material were sufficient to convince one that infantile paralysis was one of the most protean affections of the central nervous system.

A Year’s Progress in Poliomyelitis Research.

—Dr. George Draper, of New York, said that his subject called for a review of the literature, and consequently any thing that he said would be a repetition of what had already been stated. He considered only the salient points in recent literature calling attention to three in particular, the general visceral pathology, the demonstration of the virus in healthy persons, and the discovery of the organisms. In regard to the first point he said that poliomyelitis had hitherto been regarded as a disease of the central nervous system, but that lesions had been found in various viscera. The secretions of the nose and mouth which had long been suspected of being the vehicle of infection had been definitely proved to be carriers of poliomyelitis. The discovery of the greatest importance was the identification of the organism itself. This organism was extremely small. It was from 0.15 to 0.3 micron in length, and just on the limits of visibility. It was anaerobic and cultivated only with the greatest difficulty. The cultures stained best with Giemsa stain, were variable to the Gram stain, but tended to be Gram positive, varying with the constituents of the media. The organism fulfilled Koch’s laws. The interest of the moment was directed not only to the relation of the germ to poliomyelitis but to the fact that its discovery opened up a new field of bacteriology.

Dr. Henry Helman, of New York, who opened the discussion, said that when one considered that there were at least nine varieties of poliomyelitis, it was not surprising that so many atypical cases were found. Doctor Wachenheim’s cases would serve as a nucleus for many other types likely to be observed in the future. Hardly any part of the cerebrospinal system was exempt from attack, and this might account for the many types of the disease. The cerebrospinal and meningeal types were sometimes confounded with meningitis because of the presence of spasticity. After the subsidence of the spastic signs, paralysis appeared and the diagnosis became clear. It was almost impossible to give a definite prognosis in the severe cerebral forms of the disease. Since the germ was anaerobic how was it able to live in the nasal secretions or in the rectum?

Dr. H. L. Amoss, of New York, remarked that Doctor Draper had given a very good description of the organism. It was only with the greatest
difficulty that they had succeeded in cultivating it at all according to Noguchi's method. They had tried about twenty-five samples of ascitic fluid before they at last succeeded in cultivating the organism from the nervous tissues of a monkey dead of the disease. The organism had been found once in the spinal fluid of a monkey, but never, to his knowledge, in that of a human being. They had concentrated spinal fluids from several cases of acute poliomyelitis in the human being under diminished pressure at 33° C. and injected it into the brain of monkeys; suggestive symptoms alone resulted. As to the viability of the virus, one of their strains had been kept in sterile glycerin in the ice-box for twenty-four months and was still capable of producing the disease when inoculated into the brain of monkeys.

Dr. George Draper, in closing the discussion, said in reply to Dr. Heiman's question that possibly the secretions of the nose and throat formed a capsule enclosing the organism and excluding the air and thus preserved the vitality of the organism.

Dr. F. L. Wachsmuth said that the points which he wished to emphasize were the difficulties in diagnosis in meningocele cases, and that in a few days one could usually size up the case as not typical meningitis. The subject of insects as carriers of poliomyelitis had not been discussed and it was to be hoped that it would be brought up later.

Results of Investigations of Summer Diarrhea at the Boston Floating Hospital.—Dr. Henry I. Bowditch, of Boston, read this paper by invitation. He declared that greater interest had been shown in Boston than in most other cities in the bacteriology of intestinal diseases of infancy. His remarks were based on the investigations in the Boston Floating Hospital from 1910 to 1913 and illustrated the advantage of intensive work. The Floating Hospital had accommodations for 120 ward and 160 day patients. The children admitted ranged in age from one day to seven years. The first object of his hospital was to serve the public, but in addition it had attempted to produce scientific results which would be helpful to humanity.

The scientific work was started in 1909 by Dr. William P. Lucas, who with others studied agglutinins in the blood of dysenteric cases. In 1910, Dr. Arthur L. Kendall, with the cooperation of the staff, made an extensive study of diarrheas both from the bacteriological and the clinical standpoint. They established a shorter method by twenty-four hours of making the bacteriological diagnosis of the dysenteries produced by the Flexner and Shiga bacilli. They found the gas bacillus the predominating organism in many cases and then demonstrated a short clinical test for its presence in the stools. This test consisted in taking a tube, one quarter full of milk, and inoculating it with mucus from a movement. The whole was boiled over a Bunsen flame for one minute and then kept at blood heat for from six to nine hours. A positive gas bacillus infection peptonized the milk, squeezed out the whey, riddled the curd with gas, and produced a strong odor of butyric acid. This same year they shortened their former long period of starvation in dysenteries from three, five, or seven days to twenty-four hours. Boiled water was given as temporary starvation. This was followed by barley, lactose, and buttermilk, according to the infection.

In the year 1910 they used for the first time a solution of dextrose (2.5 per cent. in normal saline) for stimulation in cases of dysentery of the Flexner type with marked loss of water and depletion. It was usually injected in rather large amounts, at first four, six, and eight ounces every twelve hours. The idea underlying this procedure was that the normal amount of dextrose in the system had been partially used up and by supplying the infecting organism with this food it could be prevented from living on the body proteins and producing toxins.

In 1911, they for the first time isolated the Shiga bacillus from the blood. During this summer they made an investigation along the line of rectal irrigations, trying various solutions, most of which seemed to do little good. They now gave saline irrigations immediately on admission and but few during the course of the disease. They used silver nitrate (three per cent.) in instances where the infection was low. Solutions like tannic acid had little effect. They found that pyelitis was rather frequent in their cases, the majority of cases occurring in cases of streptococcus infection.

In 1912, the number of cases infected with the gas bacilli greatly increased, and they carried out their theory of feeding high proteids, giving buttermilk, fatfree milk, and Elweis milk without any trouble. After the first week they felt safe in giving these without making a bacteriological examination. Almost all the children improved under this treatment and one variety of milk seemed to agree as well as another. They therefore concluded that milks with high protein content were better for gas infections, and they also found that in this kind of infection it was dangerous to give lactose. If one was giving lactose and the symptoms reappeared one should change immediately to a high protein diet.

While the year 1913 was not yet complete the work was interesting as far as it went. They now made more accurate bacteriological examinations than formerly. During this year there was a predominance of the shiga bacillus. This bacillus first appeared in August, 1912. The bacterial study of these cases brought out the fact that the predominating bacillus in the month of August in one year would be the predominating one in the following July; this carried out the cyclic phenomenon of epidemic diseases. They had used during July of this year high proteid feeding on account of the presence of the gas bacilli, but in August the Flexner bacillus appeared and because of the danger of giving high proteids in such cases they quickly changed to other methods of feeding, giving lactose solutions (from five to seven per cent.) with or without barley starch.

There was a pleasing cooperation among the members of the staff of the Floating Hospital; the patients were at the service of any one of the visiting staff. They held a yearly clinical midsummer meeting in order to go on with their season's work, which proved most beneficial and to which all who were interested were welcomed.

In opening up the discussion, Dr. Richard M. Smith, of Boston, said that they had paid special
attention to the acute diseases of the gastrointestinal tract on the Floating Hospital and had tried to separate the cases into groups. They had used the classification recommended by the pediatric department of the Harvard Medical School and found it a satisfactory basis. They had seen, primarily, three large groups of patients. The first group presented simple digestive disturbances caused by errors in diet, due either to a single constituent in the food or to a combination. In this group the disease was not primarily associated with the summer months and they had studied it less intensively than the other groups. The second group included patients who had more than a simple digestive disturbance. The etiology of this group was not well understood; apparently it was not primarily due to bacterial action, though the bacteria might enter into the condition. Neither was it dependent entirely on atmospheric conditions. However, there was a small group of cases within this general division which were certainly due to great atmospheric humidity. There was a possibility that a further study of these cases would show that the weather had more to do with them than they were at present inclined to believe. The third group included cases which were true infections and were to be sharply differentiated from the other groups. The organisms responsible for individual cases varied, but the cases as a whole could be better grouped together under the term "infectious diarrhea." The type of organism showed a marked seasonal tendency, one type usually predominating in a single summer. The particular organism could not be positively determined by clinical study alone but must be determined by bacteriological examination. The pathological findings from different bacteria varied strikingly, as did also the response of individual babies to various kinds of treatment. Many of the types of organism were only partially understood, but several distinct groups were recognized, the Shiga, Flexner, and the gas bacillus. Further investigation would be necessary in order that they might reduce the undetermined organism to a minimum. Their work had been undertaken with no preconceived ideas, but they were trying to draw logical conclusions from the combined clinical, pathological, and bacteriological study of the material as it presented itself in the Floating Hospital.

Dr. Rowland G. Freeman, of New York, said that his first experience in pediatrics having been in the autopsy room, he had become accustomed to an anatomical classification. Clinically, cases were readily classified in this way. The lesion in most cases was ileocolitis, only the lower twelve inches of the ileum and each end of the colon being infected, the transverse colon being distended with gas. These cases might be acute or chronic. There might be simply a congestion or an enlargement of the follicles, or an erosion giving rise to blood in the stools. He had always looked forward to a bacteriological classification, but so far their information had been insufficient for this. For some years he had been interested in the isolation of the Flexner bacillus and in studying the results of the bacteriological examinations in large services he had felt convinced that the Flexner bacillus was simply a terminal infection and had no significance as regards prognosis or treatment. At the time, however, they were not looking for the Flexner bacillus as a predominating organism.

Dr. Godfrey R. Pisek, of New York, said that the practical point in this work was the opportunity to study a large number of cases over a long period of time. The results of this work had given them practical information. The southerner who came to their schools often asked more questions on the bacteriology of diarrheal diseases than any other, and this was because he had larger opportunities for observing that therapeutical measures that gave good results in some cases did not do so in others. The Boston men were on the right track in saying that certain bacilli were predominant in some localities and not in others. Doctor Bowditch had told them nothing of their mortality in Boston; in New York they were justly proud of their statistics of infant mortality. Doctor Pisek cited some of the figures showing what had been accomplished by various agencies in New York in the reduction of infant mortality. For instance, the mortality of children under one year of age for the year 1906 was 153.7 to each 1,000 births, while in 1912 it was 105.3. The death rate for the three months of 1913 for infants under one year of age showed an actual decrease from 1908 of 28.2 per cent.; from 1909 of 20.1 per cent.; from 1910 of 26.1 per cent.; from 1911 of 19.3 per cent.; and from 1912 of 5.7 per cent. For July, August, and September of 1912 the total number of deaths of infants under one year of age was 4,381 and for 1913 it was 4,119. The number of deaths from diarrheal diseases of children under one year of age was 1,021 for 1912, while for 1913 it was 1,088. In 1912 the infant deaths were 43.8 per cent. of all deaths, and in 1913 they were 39.7 per cent. of all deaths.

Dr. L. E. La Ferra, of New York, stated that last year he had had the privilege of making two visits to the Floating Hospital and wished to express his admiration of the work done there. All the cases were most thoroughly studied and the staff conference which he had attended was most interesting. From what had been said of the different results of using Eiweiss milk on the cases with gas bacilli and on those with the Flexner bacilli, it would seem that a knowledge of the predominating bacteria would be of distinct advantage. Occasionally they got a case that did not clear up with the Eiweiss milk, and a bacteriological examination would certainly be a help. It would be interesting to know if Doctor Bowditch had discovered any characteristic feature of the stools, as odor or reaction, that would indicate the kind of infection present.

Dr. Herman Schwarz, of Boston, observed that in the examination of a large number of stools they had found the Flexner and Shiga bacilli wherever there was blood and pus in the stools. It seemed possible that these bacilli might be the normal terminal infection of all these diarrheas.

Dr. Alfred F. Hess, of New York, said that Doctor Bowditch had not mentioned the reaction of the stools. Dr. Kendall originally emphasized the importance of this reaction. He had stated that where an acid reaction was present, one should use proteids, and where the reaction was alkaline, a
carbohydrate diet should be used. They had found, however, that in spite of an alkaline reaction the children frequently got well with proteid food. What was meant by starvation of from five to seven days? It had been stated that sugar had been suggested because this substance had partially disappeared from the blood. Was that a demonstrated fact? It was most important in these cases to give water. The drip method by the mouth, using a nipple, was very satisfactory. A quart could thus be given in a day and the method had the advantage of keeping the baby quiet.

Dr. Henry Heiman, of New York, expressed the opinion that Doctor Bowditch had proved his cases to be infectious diarrheas. All were acquainted with these bacteria as causing specific infections, but these cases must be distinguished from the so-called summer diarrheas in which there was no specific infection, but in which hundreds of saprophytes were found, the bacteria playing only a secondary rôle. At the Mount Sinai Hospital in the so-called summer diarrheas examinations for the Shiga bacilli were almost always negative; out of forty cases examined there was only one with cocci, though Gram negative bacilli were always present. It was Doctor Heiman’s belief that most cases ordinarily called summer diarrheas were not caused by specific organisms but were mostly due to nutritional disturbances with gastrointestinal symptoms in which the bacteria played only a secondary rôle.

Dr. J. Finley Bell, of Englewood, N. J., thought the work in the Floating Hospital most interesting, but said it required elaborate apparatus which was not practical in private practice. Probably a simpler method would be deduced of determining the kind of infection present. In one case of the recurring type which had come to his notice in which blood and mucus were present in the stools a diplococcus was found. Was that a distinct organism, or a streptococcus infection?

Dr. Roger H. Dennett, of New York, said he was particularly interested in the therapeutic test of determining the variety of diarrhea by feeding sugar solution. He stated that in New York many had used just the opposite therapeutic test, that of feeding high proteid mixtures as a routine, in all cases except the acute febrile dysenteries, in which gruels seemed to be indicated. In all cases except the last variety, Eiweiss milk and the strong milk and water mixtures seemed less liable to do damage and appeared more logical. Doctor Dennett asked if starches could take the place of sugars solutions. He believed that there must be some place therapeutically for the time honored barley gruel which had been used so many years in the treatment of diarrhea.

Dr. Henry I. Bowditch said that he did not intend to evade the question of mortality, and, while he had not the exact figures, he might say that in 1910 and 1911 it was high when the Flexner, Shiga, and streptococcus bacilli were predominant. The mortality in the presence of the gas bacilli, in 1912, was much less, from ten to twenty per cent. This year, 1913, it was low until August when it suddenly jumped up, due to a wave of the Flexner bacilli. Dr. Hess was correct in his idea as to the indications of acid and alkaline stools, but the reaction must be taken into consideration with the other symptoms. By starvation was meant starvation as regarded food. Water was permitted. It was their practice to give five per cent. lactose or barley water. One point that should be mentioned was the greater opportunity for them as physicians to get results from groups of cases by cooperative study. They would like it if such a group of cases could be studied in Philadelphia, New York, Boston, etc., and then they could get together and compare results and get something worthwhile from their investigations.

Letters to the Editor.

RADIAN TREATMENT.

850 Seventh Avenue.
New York, October 27, 1913.

To the Editor:

Among my applicants for the treatment of cancer and other diseases with radium, there is one containing twenty milligrammes of the most powerful radium salt, having an activity of two million. As far as consistent with my other work it is my custom not to limit the use of my radium instruments to those who can afford a fee commensurate with the expense of the outfit, the risk of loss or destruction, and the time and study devoted to the subject. On the contrary I hope to extend its benefit to many persons in moderate circumstances to whom a reduced charge will be expensive but not prohibitive.

My reason for making this announcement lies in the sense of a special duty toward the community in which one earns livelihood felt by the possessors of a remedial agent which, for the present, is so scarce.

Sinclair Tousey, M. D.

THE SENSE OF SMELL IN DIAGNOSIS.

428 Forty-seventh Street.
Brooklyn, N. Y., October 26, 1913.

To the Editor:

If Dr. Theodore Zangger will kindly look up my article on The Sense of Smell as An Aid in Diagnosis, he will find that I mention the odor of the perspiration in tuberculosis (page 124, second column, line 32) as follows: "In pulmonary tuberculosis there is a characteristic odor about the patient, aside from the odor of the breath before altered. This odor is pungent and emanates from the skin and sweat glands of the patient. It may be perceived on the underclothing after removal from the body." Hence it is easy to see that Doctor Zangger’s observations along this line agree precisely with those expressed by the writer.

The title of my paper bears out the doctor’s idea in regard to the advisability of considering "the sense of smell as a confirmation of diagnosis—the proper clinical diagnosis should precede the other." It is interesting to notice that Doctor Zangger can detect the odor of acute inceptive tuberculosis and that for years he has made a note in his register "specific odor."

Let us hope that other careful observers will follow up these observations, possibly on a larger scale.

Robert E. Coughlin, M. D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The present edition, the eleventh, is stated by the author to have been thoroughly revised, the sections on salivary secretion, the formation of urine, and a considerable portion of the section on respiration likewise. Much new matter is added, the points of the former edition being returned to, and the applications of the physical chemistry of physiology, so called vitamins and several other subjects has likewise been added, as has also the entire chapter on reproduction and development. Notwithstanding all this additional matter, the bulk of the volume has not been increased, being in fact shorter than the former edition by one page.

One cannot but deplore the paucity of progress in physiological knowledge of a kind that will aid the internist or pathologist in solving many of the problems with which he is constantly being confronted. This defect is not, of course, more evident in Halliburton's work than it is in other textbooks of the same high order; it is due to the facts that physiologists as a whole neglect such questions—the mechanisms and the variations of the functions in different individuals, the action of the vegetative system, the use of antiseptics, etc., which plays so vast a role in organic function; cardiac inhibition, which means so much to the pharmacologist, among others. These criticisms apply, we repeat, to physiology as a whole. As a textbook, Doctor Halliburton's undoubtedly ranks with the best.

Meetings of Local Medical Societies

Monday, November 14th.—Society of Medical Jurisprudence, New York; New York Ophthalmological Society; Corning Medical Association; Williamsburgh Medical Society, Brooklyn; New Rochelle Medical Society; Waterbury, Conn., Medical Association.

Tuesday, November 15th.—New York Academy of Medicine (Section in Neurology and Psychiatry); Medical Society of the County of Schenectady; Medical Society of the County of Rensselaer; Buffalo Academy of Medicine (Section in Medicine); Newburgh Bar Medical Society; New York Ophthalmological Society; Jamestown Medical Society; Rome Medical Society; Practitioners' Club of Jersey City, N. J.

Wednesday, November 16th.—New York Pathological Society; New York Surgical Society (annual); Medical Society of the Eastern District of New York; Committee of the City Hospital; Alumni Association of the Norwegian Hospital, Brooklyn; Brooklyn Medical and Pharmaceutical Association; Dunkirk and Fredonia Medical Society; Richmond County Medical Society.

Thursday, November 17th.—New York Academy of Medicine (Section in Pediatrics); Brooklyn Pathological Society; Blackwell Medical Society of Rochester, Jenkins Medical Association, Yonkers; Buffalo Ophthalmological Club; Society of Physicians of the Village of Canandaigua; Auburn City Medical Society; Physicians' Club of Middletown; Gloversville and Johnstown Medical and Surgical Association.

Friday, November 18th.—New York Academy of Medicine (Section in Otology); New York Society of Dermatology and Genito-urinary Surgery; Eastern Medical and Surgical Society of the City of New York; Society of Ex. Graduates of the College of Physicians and Surgeons of the City of New York; Brooklyn Ophthalmological Club; Buffalo Ophthalmological Club; Saratoga Medical Society.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending October 29, 1913.

Austin, H. W., Senior Surgeon. Detailed to represent the service at the fourth annual session of the
Clinical Congress of Surgeons of North America, to be held in Chicago on November 10 to 15, 1913. Cobb, J., Assistant Surgeon, was appointed to represent the service at the fourth annual session of the Clinical Congress of Surgeons of North America, to be held in Chicago on November 10 to 15, 1913. Cumming, H. S., Surgeon, Directed to proceed to the earliest convenient time to Norfolk, Va., for the purpose of making an inspection and report upon the availability of the United States Naval vessel Newark as a floating quarantine station at Providence, R. I. Frost, W. H., Passed Assistant Surgeon. Directed to attend the conference of town and county health officers of West Virginia, at Parkersburg, November 28, 1913, and present an address on the subject of the Prevention of Typhoid Fever in Town and Country. Lloyd, B. J., Surgeon. Directed to proceed to Martinsburg, W. Va., for conference and preliminary investigations of typhoid fever; upon completion of this duty to proceed to Lomaconing, Md., by October 31, 1913, to address the faculty of the school regarding measures necessary to prevent the spread of typhoid fever and other communicable diseases. Preble, Paul, Passed Assistant Surgeon. Directed, in connection with the investigation of the pollution of the Ohio river at Elgin, Ill., to go to Elgin, Ill., to examine the vicinity of sanitary surveys of localities, to locate sampling points, and to arrange for collection of samples. Ruoff, J. S., Assistant Surgeon. Relieved from the duty of the Harvey quarantine station, and directed to report at the bureau for further orders. Spratt, R. D., Passed Assistant Surgeon. Granted one month's leave of absence from October 24, 1913. White, M. J., Surgeon. Detailed to attend the annual meeting of the Ohio Valley Medical Association, November 5 and 6, 1913, at Evansville, Ind.

Casualties.

Board Convened.

Board of medical officers convened to meet at the call of the chairman at Manila, P. I., for the examination of pharmacist N. C. Comfort to determine his fitness for promotion to the grade of Pharmacist of the first class. Detail for the board: Surgeon Victor G. Heiser, chairman; Assistant Surgeon B. J. Duff, recorder.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending November 1, 1913:

Baker, David, Major, Medical Corps. Relieved from duty at Fort McPherson, Ga., to take effect upon the arrival at that post of Major Thomas S. Bratton, Medical Corps, and will then proceed to Fort Sill, Okla., for duty. Blanchard, R. M., Captain, Medical Corps. Ordered to Fort Independence during the absence of Major Wadhams. Dunbar, I. R., Captain, Medical Corps. Granted two months' leave of absence. Duncan, L. C., Captain, Medical Corps. Ordered to Fort Howard for temporary duty during the absence of Major P. C. Hutton. Qualls, G. A., First Lieutenant, Medical Corps. Joined camp at Texas City on October 21st. Smith, W. H., Captain, Medical Corps. Relieved from First Aero Squad and assigned to duty at Field Hospital No. 3, Texas City, Texas. Turnbull, S. J., First Lieutenant, Medical Corps. Relieved from Second Battalion of Engineers, and ordered to duty with Ambulance Co. No. 3, Texas City, Texas. Van Poole, G. M., Major, Medical Corps. Granted one month's leave of absence.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending November 1, 1913:

The following named assistant surgeons of the Medical Reserve Corps, commissioned from October 20, 1913, have been ordered to the Naval Medical School, Washington, D. C., for a course of instruction: W. E. Bradley, H. L. Hawwarth, Daniel Hunt, H. R. MacAllister, and T. A. Ratliff.

Deaths.

Arnold—Ingersoll. In New York, on Thursday, October 30th, Dr. Harold Sears Arnold, of New Haven, Conn., and Miss Nettie Ingersoll, of New York, on Sunday, October 22nd.

Baldwin. In Elkhorn, Neb., on Monday, October 20th, Dr. Charles W. Baldwin, aged forty-seven years.

Barnes. In Bement, Ill., on Monday, October 27th, Dr. Claude E. Barnes, of Decatur, Ill., and Miss Nettie Elder, of Chicago, on Sunday, October 19th, Dr. Thomas A. Elder, of Wooster, Ohio.

Budin. In Milan, Texas, on Tuesday, October 21st, Dr. John W. H. Hudson, aged sixty-eight years.

James. In Louisville, Ky., on Wednesday, October 22nd, Dr. Thomas James, aged thirty-five years.

KEYES. In Lecroy, Ill., on Wednesday, October 22nd, Dr. Thomas W. Keyes, aged seventy-five years.

Lynn. In Hasting, Neb., on Saturday, October 18th, Dr. William H. Lynn, of Mills. In Louisville, Ky., on Friday, October 24th, Dr. Samuel B. Mills, aged eighty-five years.

Mosgrove. In Urbana, Ohio, on Wednesday, October 19th, Dr. G. S. Mosgrove, aged fifty-eight years.

Newlin. In McKeensport, Pa., on Sunday, October 19th, Dr. Harry S. Newlin, aged fifty-five years.

Peterson. In Chicago, on Monday, October 20th, Dr. Herman F. Peterson.

Rader. In St. Louis, Mo., on Wednesday, October 22nd, Dr. John M. Rader, aged fifty-four years.

Todd. In Pottstown, Pa., on Monday, October 27th, Dr. John Todd, aged eighty-four years.

Wood. In Lakewood, N. J., on Saturday, October 29th, Dr. Allen L. Wood, aged seventy-three years.
Original Communications.

THE FAMILY SUBSTANCE AND THE THEORY OF COINCIDENT DISEASE IN BLOOD RELATIONS.

BY BAYARD HOLMES, M. D.

Chicago.

The trend toward mysticism in our time is marked. It appears in the field of the intellect, in religion, and in art. Professor Harold Höffding, of Copenhagen, declared at a recent congress of psychologists that since all the most important problems were beyond the reach of man’s reasoning power, a search for ultimate reality led inevitably to mysticism. Henry Bergson, the French Jewish philosopher, whose speculations have deeply influenced the whole thought atmosphere of the day, shows decided mystical leanings. Symbolism is the keynote of modern drama, the watchword of Ibsen, Hauptmann, and Maeterlinck, and symbolism, we are often told, is only another name for mysticism.

In spite of its pervasiveness very few persons can define mysticism. There is a mystical tradition extending for many centuries back to Egyptian civilization, through Clement of Alexandria, St. Basil, St. Bernard of Clairvaux, Bonaventure, St. Francis of Assisi, Thomas a Kempis, St. Catherine, Fenelon. Mme. Guyon, Henry More, George Fox, Sigmund Freud, Wilhelm Fliess, and a great army of pseudo-scientists, known only to their own several cults.

J. Ellis McTaggart, in the New London Quarterly, gives a very comprehensive definition of mysticism:

It seems to me that the essential characteristics of mysticism are two in number. In the first place it is essential to mysticism that it assert a greater unity in the universe than that which is recognized in ordinary experience or in science. However apart this unity is, how far it excludes differentiation, are questions which would be answered differently by different mystics. What is essential is the affirmation of a unity greater than that which is usually acknowledged.

The second essential characteristic of mysticism is the affirmation that it is possible to be conscious of this unity in some manner which brings the knower into closer and more direct relation with what is known than can be done in ordinary discursive thought.

We are all familiar with the comprehensive theory of Sigmund Freud, and with the extensions which this theory has received in the hands of his multiplying admirers, both in Germany and in America. It is distinctly a mystical theory in susceptible of either proof or refutation. It includes many excursions into the intangible and the mystical, especially in the direction of dreams and of pathological psychology. Those who are able to read Freud’s theories and the numerous illustrations which he puts forth as confirmatory of them, without an attack of mental indigestion or an intellectual crisis, may perhaps be able to read the theory of the family substance which was put forth by Wilhelm Fliess in 1906, in a beautiful volume entitled Der Ablauf des Lebens, Grundlagen zur Exakten Biologie (Franz Deutieke, in Leipzig).

This book contains eight pages of assumptions, and 584 pages of illustrations of these assumptions, somewhat after the manner of Freud. It is the most remarkable mystical, mathematical, and biological compilation of modern times, and resembles the symbolic mysteries of Egyptian mathematics and Egyptian medicine.

It appears that Fliess discovered that women menstruate regularly once in twenty-eight days and that many of them have irregular menstruations, which can be easily made to correspond with nodes produced by the coincident, or aggregated, or interfering rhythms of twenty-eight and twenty-three days.

He takes as an illustration Fräulein H., who menstruated on March 22, 1896, and following that at intervals of twenty-three, twenty-one, twenty-six, twenty-four, twenty-one, twenty-five, sixteen, sixteen, thirteen, and twenty-two days, the last time upon October 15th of the same year. Now the normal interval of menstruation is twenty-eight days, but it is not once apparent in this sequence. If, however, we take seven periods beginning with April 14th, and ending with October 15th, and omit considering the other menstruations, we have the following series: 23, 47, 24, 46, 45, 22, which are equal to the following series respectively: $1x23$, $(2x23)+1$, $(1x23)+1$, $(2x23)-1$, $(1x23)-1$.

If we make a sum of these factors we find that it is equal to $9x23$. In these seven terms then we have a distinct interval of twenty-three days, with a possible error of a plus or minus 1. Now, taking the remaining terms, May 5th to August 25th—which is equal to 112 days, or $4\times28$ days, and the terms between July 15th and September 10th—which is fifty-seven days, equal to $2\times28$ days, we see that in the exceptional menstruations which rendered the whole series irregular and caused it to apparently depart very strongly from the regular menstrual period of twenty-eight days, that these four intervals exceed the regular interval by only one Jay.

From such a system of examining irregular menstruations Fliess comes to the conclusion that there is in each individual a family substance having a male and a female manifestation, the rhythm of the former being twenty-three days from node to node, while the latter is twenty-eight days.

He shows further that the eruption of the teeth in the children, the appearance of menstruation in the
NASCHER: MEDICAL CARE OF THE AGED.

Girls, and the various sicknesses of both the boys and the girls stand in a remarkable coincidence to the menstruation of the mother.

The period of gestation is shown by Fliess to be a multiple of twenty-eight and twenty-three, and furthermore, that the appearance of the next pregnancy, the next gestation, and the next birth correspond similarly with these mystical numbers. In this manner he follows out the complete history of Sigmund Freud's family and that of many of the most celebrated and best-known characters in Europe.

He gives an illustration of epileptics who have their epileptic attacks beginning after intervals of $571 \times 28$ days after birth and occurring after that time at intervals readily measured by twenty-eight or twenty-three days. In further examples he shows that measles, pneumonia, scarlet fever, and many other infections appear at intervals, measured by these mystical numbers.

Perhaps one of the most remarkable examples (example xxxiv) is that of Herr Ecke, who was born November 26, 1834, and on January 27, 1891, had an attack of gout. From that time on he had nine attacks of migraine and then an epileptiform attack. At last, on November 15, 1896, he had an attack of hemiplegia with aphasia, and died on March 11, 1897. It takes twenty-five pages of complicated mathematical formulæ to show that these events, which occurred at the latter end of a life of 22,751 days, are commensurate with the mystical numbers twenty-three and twenty-eight, and that each event occurred at one of the nodes which disturbed the family substance.

In examples xxxv et seq., he gives illustrations of the coincident diseases of several members of the same family and from these examples deduces his theory of family substance. The most striking one is that of the Fliess family, where he naturally has had the best opportunities of making observations. The 125 or 130 pages devoted to this demonstration appeal largely on account of their bulk and on account of the introduction of numerous functions represented by the Greek letters of the alphabet, and by complicated formulæ.

Fliess also takes great bulbs of statistics of stillbirths and of twins and triplets, and reduces them to conformity with the mystical numbers twenty-eight and twenty-three.

In order to facilitate the explanation of facts by his theory, he has added a series of formulae and tables occupying ten pages.

Arnold Siegmund, in the *Annalen der Naturphilosophie*, I, p. 35, has devoted a large amount of space and a great redundancy of illustrations to demonstrate simultaneous sickness of blood relations. His observations are in support of Fliess's theory of the family substance. It is hardly worth while to give more than a few of his assertions. When, as a laryngologist he is called to see a sick child at the grandmother's house, he is obliged, in order to treat the child properly, after making a diagnosis of laryngitis, to discover the condition of the family substance by telephoning to the mother and to the school where the brothers are placed. If he prescribes for hives in a child, the castor oil must be given not only to the infant but to the father, the mother, the sisters, the brothers and the uncles and the aunts. If the father and mother are traveling and one of them is attacked with colic, he recommends that the telegraph and telephone be freely used to discover the condition of the children at home. In other words, it is necessary to treat the family substance wherever it exists, whenever any member of the family is discovered to be ill.

The multitude of his illustrations seem to appeal to his method of thought, although to those who hold to a materialistic philosophy, there is no more reason in the sequence of words than there is in the effusions of a maniac.

Fliess replies to his silent critics at great length (*Annalen der Naturphilosophie*, x, pp. 314-50), and closes with the following significant words, which I closely translate:

"My researches have had a singular fate. In them life is shown for the first time as a function of our planet and as rhythmical with its two great periods, the time of revolution, the day, and the time of rotation, the year. These functions were demonstrated specifically and phenomenally in a great number of the most various organisms. New lights fell thereby upon the existence of the two sexes, upon bilateral symmetry, upon procreation and growth, upon birth and death. Problems of the very first order where touched upon and connections were found between them which before seemed so far apart. The book proceeds from the primum movens to the last. My researches delineate the revolutionary history of the world and prove the existence of a teleological natural law with a teleological interpretation."

*Opening address of the Thirty-fourth Annual Session of the College of Physicians and Surgeons, Boston, September 17, 1913.*
the medical profession—the care of the aged. I shall go beyond the scope of the title and consider the institutional and home care as well as the medical care of the aged, as these are correlated.

The care of the aged involves many difficult problems, problems in sociology, in psychology, in economics, philanthropy, and medicine. These are often so closely interwoven that it is impossible to consider one without bringing in the others. It is probably for this reason, and for the reason that there are few who can deal with these problems collectively, that we have gotten into a laissez faire attitude, an attitude of indifference in regard to the aged, looking upon them only as an economic burden which we must bear for humanitarian reasons. In the institutions and in the home the aged are treated by the community at large, by the family, and by the medical profession as they were treated a generation and a century ago. Whatever advances have been made in their betterment have been incidental to the general progress of civilization, and not to any direct effort to improve their mental, physical or material condition. The old man dependent upon the bounty of the community still goes to the workhouse or poorhouse, a pauper. He is treated as a pauper, lives as a pauper, and dies as a pauper, unpitied, uncared for. You know the ancient quatrain, "Rattle his bones over the stones, he is only a pauper whom nobody owns." Nobody owns the pauper. The child dependent has the world for its guardian; the aged dependent is disowned by his own.

It is but little better in the home. So long as the old man and the old woman are able to support themselves and look after their own welfare they are endured with more or less cheerfulness. Let them become dependent and they are at once an unwelcome burden. It is then noticed that the old man cannot readily accommodate himself to the new order of things and he is called "old fashioned." Owing to increasing forgetfulness, he leaves his clothes on the chair and paper scraps on the floor, and the housewife who has now additional work, calls him a nuisance. The old woman who adheres to her old ideas and decrees modern dress, customs, and unconventionalities, is "cranky," while if she tries to adapt herself to modern ideas and wants to keep up with the spirit of the times in dress and customs she is called "giddy." Where the old folks cause hardship to the breadwinners they become financial burdens, the more unwelcome if the bread they eat must be taken from the mouths of the younger members of the family. They are burdens from whatever standpoint we view them, social or economic burdens, often both.

The economic factor is the most important factor in every day life and we gauge the desirability of men and things by their economic value. The child has a prospective economic value. The aged individual is an ever increasing economic deficit from the moment that the value of his consumption exceeds the value of his production. It is true that some men have continued to be economic assets until extreme old age. We find them in every field of thought and human endeavor except where brute strength is involved. Among statesmen we could mention von Bismarck, Gladstone, Disraeli, Thiers, von Metternich, Franklin, and Clay. Among scientists are Galileo, von Humboldt, de Buffon, Darwin, Spencer, Harvey, Euler, and Von Baer. Tintoretto, Perugino, Titian, Cukiushkan, and West, among painters; Verdi, Rossini, Meyerbeer, Handel, among musicians—all did remarkable work after their seventieth year. In our own profession there were many and there are still many to-day who have passed the biblical limit of threescore years and ten, yet are active and add to the general store of medicine their knowledge gained by sage experience. But these are all exceptions to the rule that when a man reaches the period of decline he soon becomes an economic burden. It needs no political economist who deals in values, reducing values to figures attached to a dollar sign, to show that the aged are and will continue to be economic burdens.

The aged themselves feel that they are no longer as valuable to humanity, to the community, or to their family as they were formerly. But they also feel that there is no sentiment in figures, that the world has little time to waste upon those who cannot add to the world's stores, be it in knowledge, work, or tangible goods.

The family still looks after its aged members, though more often from a sense of duty or fear of condemnation than from gratitude or filial affection. The State looks after its dependents, with pity for the helpless child in the asylum, with sympathy for the charity patient in the hospital, with indifference for the aged pauper in the almshouse. Visit the public institutions for these three classes of dependents. Compare the cheery rooms, the pleasant surroundings, the solicitous care taken of the inmates of children's homes; see what efforts are made to relieve the patients in the hospitals and make them more cheerful and happy; then go to the almshouse and observe the poor aged wretches sitting about on pine benches, often unattended, generally neglected, awaiting the final summons, with a helpless, haunting fear.

Those who have never given a thought to this subject cannot realize the utter neglect of the aged by the medical profession. There is perhaps no other branch of science which has made greater strides in a single generation, certainly none which has done more to increase the happiness of mankind by diminishing pain and prolonging life. The death rate has been reduced over forty per cent. between birth and forty-five years of age. Some of the most fatal diseases of early life have been brought under control. The study of child nutrition has altered our views as to infant feeding; and gastrointestinal diseases and diseases of malnutrition have diminished. The study of child psychology has revolutionized educational methods. The physical development of the young has received attention in late years such as has not been given to it since the days of ancient Rome. The diseases of early life have been studied by specialists who have devoted their lives to this subject and pediatrics has now become one of the most important branches of medicine. International congresses have been held to discuss the welfare of the young. There are innumerable homes for children, most
of them upheld by private philanthropy. There are children's hospitals and there is hardly a general hospital which has not its children's ward.

What has been done by the medical profession for the aged? While childhood is recognized as a physiological entity, and considered apart from maturity, physicians still look upon old age as a pathological state of maturity, though the anatomical and functional differences between senility and maturity are greater than between childhood and maturity. The diseases of old age are still treated as diseases of maturity complicated by degenerations, instead of diseases in normally degenerating organs and tissues. And when our misdirected efforts fail, we fall back upon "old age" as a diagnosis and an excuse for our failure. Does the pediatrician, called to a child suffering from difficult den- tion, say the child is suffering from childhood? Yet the physician seeing a patient with senile arteriosclerosis will say he is suffering from old age, and he will dismiss the case perhaps with a placebo. Old age is not a disease, though the term is a handy cover for ignorance. Death from old age, that is, physiological death, is very rare, far rarer than statistics indicate, since physicians include under this heading deaths among the aged who gave no clearly defined symptoms of a diseased organ or tissue, or where the symptoms were uninterpretable. Yet physiological death would occur far more frequently if we gave to geriatrics but a title of the study that we now give to pediatrics. At the present moment there is not a hospital, a ward, or a bed (outside of the homes for the aged) set aside for senile diseases.

There are but few physicians in this country who take any special interest in the aged, or who make a special study of the senile organism. I do not know of any medical school, except this, in which lectures on geriatrics are given. Not a single work on the subject has appeared in this country in over thirty years, yet there are scores of French and German works on senile diseases. I will not attempt to explain why the medical profession in this country has so utterly neglected the aged and their ailments, but will leave it to you to furnish the explanation.

I will not touch upon the diseases of old age here as these will be taken up in my course of lectures, but will mention a few measures which can be applied to the aged, whether well or ill, in the institution or in the home, to better their mental and physical condition. We cannot deal successfully with the aged unless we understand the altered mentality of old people. This change begins at the moment that the individual finds that he is aging. It may be the finding of a few gray hairs, shortness of breath when going up stairs or walking fast, more rapid fatigue, or lessened ability to perform the ordinary labors. It may be the recognition of lessened sexual virility. Whatever may have been the initial cause, from the moment that he realizes that he is on the downward path his thoughts run to the abyss that lies at the end. The realization comes as a shock and produces a mental depression which cannot be shaken off except in forgetfulness. From this moment the individual's thoughts revert to himself, and while he may continue in his accus- tomed routine of life, with advancing age he becomes self conscious and more concerned about himself, becomes more sensitive to the petty infirmities of age, develops an intense conscious desire to live. Resigned to die? Yes, but it is the resigna- tion to the inevitable, the resignation that comes with the knowledge of absolute impotence. It is a helpless resignation from which develop apathy and melancholy.

Much can be done to overcome the mental depression of the aged. I have repeatedly referred to the beneficial psychic effect of flattery and of the stimulation of the sense of pride in appearance, even to the extent of arousing a spirit of vanity. How much more pleasing is the appearance of the old woman who has taken care of her skin and hair and dresses tastily than of the old woman who makes no effort to improve her appearance. The same applies to the old man. Induce him to make the effort to improve his appearance; stimulate his sense of pride and let those around him tell him how young he looks. The psychic effect is instantaneous. Association with the young has a rejuvenating effect, and if the young people treat the aged as one of themselves, it will arouse a youthful spirit in the old folks. I have recommended sexual relations between the aged and the young. Notwithstanding the criticism this has aroused I still maintain that the courtship, and marriage of an old man to a young woman will produce a marked mental rejuvenescence and it will improve the objective and subjective manifestations of age. The reverse, the marriage of an elderly woman with a man younger than herself, will have the same effect upon the woman. There is no basis of fact in the belief that such rejuvenescence is brought about at the expense of vitality or virility on the part of the younger person. The infant does not age when lying with its mother, nor does the mother feel younger as a result of having her child with her. We can make the aged feel younger by playing upon their vanity and we can cause them to look younger by instilling into them the sense of neat- ness and pride in appearance.

We must make an effort to keep their minds pleasantly occupied. If they have nothing to do they think of their past and the future, and they brood. A commissioner of charities of New York city who realized that light physical work which would at the same time engross the attention, would keep their minds pleasantly occupied, established a city farm. Here the aged people could do such light work as they were able, take care of plants, discuss their work, and take an interest in every day affairs. This was one of the most benef- ficial measures ever adopted in an almshouse. Change of environment and scene, recreations, pastimes, and amusements have all a psychic effect and sometimes a marked physical effect. But their proper application requires a knowledge of the senile mind and organism. Young persons can climb mountains without injurious effect, but let an old man go from the seashore to an elevation of 2,000 feet and, if unaccustomed to the rarefied air, dyspnea will develop before he reaches the top and his senile emphysema will be aggravated. The salt air of the seashore is irritating to the inland
dwellers, and will aggravate a chronic hypertrophic bronchitis, though it is beneficial in the atrophic form. Change of scene may be beneficial or injurious. Coming from the country to a large commercial city, the individual is intensely interested, but in a few minutes or hours mental confusion sets in, and if this is prolonged dementia will follow.

Recreations for the aged follow the principle that the recreation should be the antithesis to the work which necessitates it. Here again we must consider the capacity of the senile mind and body. Active physical exercise is the proper recreation from mental labor, but as the aged individual usually carries on his mental labor till brain fog forces him to cease and he cannot take active physical exercise, he falls asleep. Yet some physical exercise is necessary to prevent stiffening of the joints and to produce the stimulation of the circulation required to carry on properly the metabolic processes. Mental confusion and early brain fog show mental deterioration and they cause further brain degeneration. The old man falls asleep at the sermon or play, not through inattention or lack of interest, but through excessive attention which causes brain fog. Simple melodies are pleasing while a Wagnerian composition will soon produce mental confusion. For the same reason the ball with its riot of motion is objectionable, but not the ballet with its pleasing combination of colors and its harmonious rhythmic dances. Emotional plays, and plays with intricate plots, soon tire, while the old man will sit through a musical comedy, pleased and benefited. Here let me explain the old stage joke about the baldhead row, the front row, at the theatre. The old man who has usually a presbyopia and a presbyacussia must get close to the speakers to see and hear well. Imagination may be stimulated but he seeks the sensuous rather than the sensual impressions, and when sight and hearing are weakened he will get a front row seat, notwithstanding the implied reflection upon the motive. The musical comedy, with its flimsy plot, pretty women, catchy airs, harmonious colors, and simple dances, is the best form of amusement for the aged. If they cannot afford to get a front seat, let them go to the humble stepchild of the musical comedy, the burlesque show. In spite of old prejudices this form of dramatic performance is less likely to demoralize the aged (or the young, either) than many of the modern society plays, and the aged who cannot afford the more fashionable musical comedy will derive as much pleasure and benefit from the burlesque. The circus is confusing. An old, familiar air often acts as a powerful stimulant to rouse an aged person from depressing apathy. Among pastimes, harmless hobbies should be encouraged. Hunting and fishing are excellent pastimes for the aged, while such simple outdoor sports as bowls and croquet can be indulged in by both sexes. Indoor games which do not require much calculation keep the mind pleasantly employed and do not fatigue.

And while the physician is looking after the hygienic side of the old man's welfare, he should not neglect the strictly medical precautions. He should inform the family that the actions and the appearance of the aged individual are more certain indications of the condition of his health than his statements. The family should know that there may be fever in spite of a cool forehead, that mumbling in sleep is often delirium, that when the old man or woman shows a disinclination to get out of bed at the usual hour it usually means a serious disease, though the patient does not complain of pain or other discomfort than weakness. Every symptom arising suddenly, even the sudden relief from a symptom, as sudden relief from dyspnea, is a grave omen. The family should know that the absence of pain does not exclude a disease which is usually painful, the absence of surface elevation of temperature does not exclude fever, the absence of cough does not exclude pneumonia, the absence of the accustomed snore does not exclude a coma from which the patient will never awake.

The physician in dealing with the aged should apply to them the principles which he applies to the child, the principles which underlie the practice of medicine, sympathy and science; sympathy, to relieve distress wherever he may find it; science, to study life and how to prolong it. The aged need more than the sympathy and the science of the physician. They need the support of the humanitarian, the altruist who will help them, cheer them, and make them happy. Happiness is, after all, the ultimate aim of humanity. Let the physician carry out to the full the principles that underlie his profession. Let him add the spirit of the humanitarian. Let him study the aged and their ailments, and apply his knowledge to relieve and cheer them. And though his reward may not be in tangible form, he will value the more and retain the longer the soul satisfying gift of his patient, the simple "God bless you!"

631 East 168th Street.

THE SEXUAL THEORIES FORMED IN EARLY CHILDHOOD, AND THEIR ROLE IN THE PSYCHONEUROSES.*

By H. W. Frink, M. D.,
New York.

From the Department of Neurology, Cornell Medical College.

The rather general opinion that, as Freud phrases it, "the sexual instinct enters into the child at puberty as the devils in the gospel entered into the swine" (1) is gradually being abandoned. The works of Freud, Ellis (2), Hall (3), Moll (4), and others not only contain overwhelming proof of the proposition that the beginnings of the sexual life in the child long antedate puberty, but point out that, although the very existence of such a field for investigation may have once been denied, the study of the sexual psychology of this early period is of great importance. In view, therefore, of the attitude of these high authorities no apology is necessary for the theme to which this paper is devoted.

The purposes of the paper are two. First, to present an outline of some of the opinions formed

*Read before the New York Psychoanalytic Society, January 28, 1913.
by children in regard to the great facts of human reproduction. Second, to show the part that these childhood hypotheses may play in the neuroses of later life, and to emphasize the necessity of a knowledge of the former as a prerequisite to the understanding of the latter. To accomplish the first purpose I have borrowed freely from the writings of Freud. While to carry out the second I have cited some cases from my own practice. No attempt has been made to accompany the statements made in the first part of the paper by any sort of proof. It is perhaps best to state, therefore, that the generalizations herein set forth are not the result of a few isolated observations, but the result of Freud's study of a large amount of material. It may be said further, that the observations and deductions herein described have been well confirmed by investigators in all parts of the medical world.

It appears that during the first two or three years of life children take the existence of themselves, their parents, and their acquaintances as a matter of course, and display no particular curiosity as to the differences between the two sexes in appearance, dress, and behavior. But psychoanalytical investigation seems to show that children at a little later age—perhaps most commonly in the fourth or fifth year—manifest a decided interest in all these matters and pass through a definite "period of sexual investigation." However, the desire for knowledge which appears at this time probably does not awake spontaneously. Apparently it results primarily in response to certain stimuli from without; secondarily, from a feeling within. The stimuli from without are furnished, in typical cases, by the advent of a new baby in the house. Id. The inner feeling aroused thereby is that of jealousy. The average four year old child looks upon a baby, not as a desirable addition to the family, but as a most unattractive intruder with whom in future he must share importance, worldly possessions, and, above all, parental love. By the often ill concealed feelings of hostility and jealousy born of such considerations the child is naturally led to ask himself the important question, "Where do babies come from?" But this question, judging from certain analyses of children, is not one of simple curiosity alone. Another, and possibly more important source, seems to be the child's hope that a satisfactory answer may place him in a position to prevent any repetition of that occurrence which has impressed him so unfavorably. In an emergency of this kind the small investigator naturally turns first to his parents, a source of aid and information hitherto found reliable. But in most cases he gets little satisfaction; his questions meet with either a laughing and evasive answer, an admonition not to speak of such matters, or an interesting statement such as, "The stork brings children," or, "The doctor finds them in the woods." These three typical answers affect children in much the same way. The stork or the doctor story is soon doubted and, like admonition or other evasion, merely serves to give the child the impression that the theme of birth is one to be avoided in the presence of adults. This impression, instead of removing his curiosity, simply causes him to conceal it, and to pursue any further investigations in a less open and direct manner. At the same time the failure of the parents to aid and instruct him in a matter of so serious moment gives rise in his mind to more or less distinct feelings of resentment, suspicion, and distrust.

Then, since the parents will not explain birth for him, the child attempts to explain it for himself. In secret he ponders the problem, and, from watching his elders, from seeing the sexual acts of animals, from the examination of his own body, from certain physical sensations, from vague impulses, inclinations, and longings that begin to stir within him, he collects material, and from it constructs his own theories of reproduction, which, though grotesque and faulty, are surprisingly near the truth. The content of some of these theories we will now consider.

Practically all children who form any theory whatever come to the conclusion in the one important particular that the baby grows in the abdomen of the mother. How this conclusion is so frequently reached it is difficult to say. It is certain that some children, even very young ones, connect the arrival of a baby with the precedent enlargement of the mother's abdomen. But in some cases there is no history that a birth took place anywhere within the child's range of observation until after his sixth or seventh year. Nevertheless, in these same individuals there occasionally is evidence of the early formation of theories which include the conception of the intraabdominal origin of infants. It is of course, possible that these children had seen pregnant women and forgotten it, but there are some cases which almost tempt one to think that the child has some intuitive realization of this great fact of the physiology of reproduction. It would seem, upon first thought, that if children were able to guess that babies came from inside the mother's body, the formation of correct conceptions of impregnation and birth would ordinarily follow. Yet such is not the case, for by certain faulty premises the infant theorist is led widely astray. The first of these erroneous premises is the theory, very commonly entertained, that every human being, female as well as male, possesses a penis. That such a belief should exist among small boys who have never seen the female genitals is not at all strange. But even those who have seen the genitals of some small female member of the family still cling to this notion and reconcile their preconceived views with the actual evidence to the contrary in some such way as this: "She is still little; when she gets older it will grow." Some little girls also have a similar penis theory, for, after having seen the male organ, they conclude that they too are entitled to a like appendage. Thus a little girl, one of my patients, felt very much hurt when she found that her brothers possessed a protuberance which she lacked, and repeatedly begged her mother to remedy the defect by "buying one like that from the doctor." Because of the penis theory and through ignorance either of the existence or of the functions of the vagina, the investigating child is prevented from guessing cor-
rectly the route by which the baby reaches the outer world. Consequently, the most natural conclusion is that the baby makes its exit from the abdomen through the same opening as do other solid products of bodily activity—in short, through birth, via the rectum (the "cloaca theory"). In this connection it must be remembered that children of an age to form such theories would feel toward this hypothesis none of the esthetic objections which must occur at once to an adult. "Then," as Freud says, "defecation was something that in the nursery could be spoken of without reserve; the child had not yet divorced himself from his constitutional coprophilic tendencies; it was no degradation to come into the world like a mass of excrement (5). Since the cloaca theory does not contain the concept of anatomical differences between the sexes, the supposition naturally results that males as well as females can bear children. Thus Freud's five year old patient, little Hans, remarks, "I'll have a little girl," and when his father answers, "But a boy can't give birth to a little girl," Hans replies, "Oh yes, a boy gets a girl and a girl gets a boy" (6). I once heard a boy of five say to his nurse, "When I get big I'm going to marry Will" (an older boy whom he much admired). When the nurse smilingly said, "But you and Will never could have children," the boy replied, with great superiority, "Why of course we could! Why not?" This remark was construed by the parents as evidence of the boy's complete innocence of all ideas concerning sex. A different construction could, I think, be put upon it.

Now, when the child has answered to his satisfaction the questions of where the baby develops and how it reaches the outer world, there remains another riddle to be solved. What starts the process? How does the baby get into the mother? The explanation most obvious to the child's mind is, that since the baby comes out like feces, it must go in like food. Therefore, to start a pregnancy the mother must eat or drink something,—a fruit or seed, or something furnished by the doctor,—and from this substance the baby develops. This belief is strengthened if the child learns that rain and manure are required for the proper development of seeds planted in the ground. He reasons by analogy that urine and feces must be designed to favor in like manner the development of a "baby seed" within the abdomen.

A theory somewhat different from these already described is formed by children who, through sharing their parents' sleeping room or in some other way, happen to see or hear the act of sexual intercourse. From such an experience they often derive the so called "sadistic" conception of coitus. "They see in it something that the stronger does, by force, to the weaker; and they compare it (boys especially) to a scuffle such as those with which they are acquainted from their association with other children" (5). One of my patients who distinctly remembers seeing the coitus of her parents when she was five or six years old, expresses rather typically the impression sometimes made upon the child spectator. She says: "I thought they were fighting; I was afraid; nevertheless, I thought they must love each other a great deal and that I should like to have some one love me as much." It seems probable that some children recognize the true significance of coitus and assume a connection between it and the phenomenon of birth. But a larger number apparently do not guess this connection, and, therefore, look upon the act simply as one of violence. In children who have strong sadistic or masochistic tendencies (as did the patient just mentioned) such a conception may occasion no displeasure. The tendency of children to regard coitus as a sort of assault and battery committed by the male is strengthened if they see the apparently hostile sexual activities of fowls, cats, and other animals, or if they find blood spots in the bed or upon the linen of some woman in the family. Added to this is the fact that in certain homes the entire married life presents to the observant child the spectacle of continuous strife, expressing itself in loud words and hostile demeanor. From this he takes it as a matter of course that the quarrel is continued into the night, and is decided by the same means that he is accustomed to employ with his brothers, sisters, or playmates (5).

A theory less common than any of these already mentioned is described by Reitler in the Zentralblatt für Psychoanalyse (7). Reitler had a patient, a single woman of forty-two, whose chief symptom was a peculiar insomnia. The patient described the insomnia as the result of her supersensitiveness of hearing. Any noise, even the slightest, was sufficient to awaken her and to prevent her from going to sleep again. On account of this, her place of residence was shifted to a street which was entirely unfrequented by vehicles and, as far as possible, deserted. Moreover, she rented the top story in order that there might be no tenants over her sleeping room to disturb the nightly quiet. For the same reason, the dwelling rooms adjoining her bedroom had to be unoccupied. All doors were protected by portières; the double windows, which remained tightly shut even during the hottest summer, were hung sound proof with thick curtains and drapery. But these and other measures of defence, such as stopping up her ears with wax, were of no avail; she remained sleepless. As the analysis went on, it became more and more evident that the patient's insomnia resulted not from being disturbed by actual noises as she had first stated, but from a fear of noises. Reitler concluded that this fear represented the partial return from repression of a wish which concerned some sort of noise. He first thought the symptom might be due to the patient's having heard as a child the coitus of her parents, but ultimately this theory proved untenable. The true meaning of the fear was finally discovered from the analysis of two of the patient's suicide fantasies. In one she imagined killing herself with an army revolver that had belonged to her father; in the other, she fancied herself turning on the gas from a horizontal jet in her room and being found there dead in the morning. Behind these fancies, as is usually the case, was an erotic symbolism. The revolver and the horizontal gas jet represented the penis; death meant love. But further investigation showed that there was greater effective emphasis upon the sound of the revolver and the sound of the escap-
FRINK: SEXUAL THEORIES IN CHILDHOOD.

ing gas than upon any other part of the fantasies. Finally there came to the patient a memory picture which solved the riddle of the insomnia. When she was about seven years old she had arisen early one morning and quietly stolen into the room where her parents were sleeping in a double bed. Her father lay with the covers thrown back so that she saw his naked buttocks. She crept out again without waking her parents, but upon returning to her own bed and pondering over what she had seen, she came to a conclusion of the following nature: "When the parents do that secret thing of which children may not know, they must press their naked buttocks together and blow wind into each other." This was the patient's early theory of the impregnating act. Her fear of all nightly sounds concealed by generalization a fear of one particular kind of sound and corresponded to repressed erotic wishes. The analysis based upon this conclusion caused the insomnia to disappear.

Such are some of the theories formed in the first period of childhood. In them, there is little variety; most children construct one or another of a few typical theories. But this lack of variety need cause us no surprise if we remember that these hypotheses are to a much greater extent the expression of the dominant sexual components of the child's constitution rather than the result of external impressions.

This early period of sexual investigation and theory formation ordinarily comes to an end with the beginning of the latency period. At that point the theories are usually abandoned, repression sets in, and by means of repression they are more or less excluded from conscious memory. It is on this account that many adults are unable to recall that they ever had any views upon or interest in sexual matters in early childhood. The repression of the investigating impulse goes so far in some cases that a permanent inhibition of sexual curiosity results. On this account we often find, particularly in women, not only a seemingly profound ignorance of all matters of sex, but also a striking inability to make even the most obvious deductions in regard to such things.

During the latency period, and consequent upon the quiescence of the investigating instinct, children often accept without any particular conscious doubt the stories that babies are brought by the stork or the doctor, or else they conclude that God makes some mysterious and supernatural arrangement by which infants appear in the homes of the married. These beliefs then remain in consciousness and are recalled in after life as if they were the only ones that existed in childhood.

In most children, at the close of the latency period (ordinarily, at some time between the eighth and eleventh years), the dormant sexual curiosity again appears, and a second period of sexual investigation begins. But the conditions are now quite different from those of the first period. Children now discuss matters of sex with each other; the older and better informed share their knowledge with the younger, or, occasionally, more or less complete sex instruction is given by parents or teachers. In some cases, children thus learn the whole truth about reproduction, but, more often, the child is either ignorant or misinformed concerning one or more important facts and is thus prevented from drawing correct conclusions. Consequently, the theories formed at this time are often extremely absurd and, because they are based upon such various external conditions, they are of infinite variety. To be sure, a partial revival of the earlier theories may occur and serve to color or modify later conclusions, but the typicality of the primary and, so to speak, endogenous theories no longer exists.

As these later theories are from the medical standpoint of much less importance than the earlier ones, I shall limit myself to making little more than a brief mention of a few of them. One of the most frequently found secondary theories is the belief that birth takes place through the umbilicus, through the linea alba, or through an artificial abdominal opening made by a doctor. To my personal knowledge even grown women occasionally entertain some such view. Such conceptions are really remnants of the cloaca theory. When repression of the anal and coprophilic interests occurs the original cloaca theory becomes objectionable and is excluded from consciousness. Then some less objectionable part of the abdomen, such as the umbilicus, takes in the new theory the place formerly occupied by the perineal region. One set of secondary theories depends upon the fact that many children, though no longer in ignorance of the existence of the vagina, have not yet learned of the seminal fluid. Hence, in some cases, they conclude that the urine possesses the power of fertilization; in others, that mere contact of the male and female genitals (without penetration) is all that is necessary for impregnation. According to my experience, the latter, or "contagion theory," is found only among females. Other beliefs that might be mentioned are the following: That impregnation results from kissing, that coitus takes place by rectum, that birth follows invariably or immediately after coitus, etc. One of my patients, apparently believing that some close analogy existed between human copulation and the incubation of eggs, concluded that intercourse had to take place every night for nine months in order to produce a child.

In great part, the preceding pages represent a partial review of some observations published by Freud in 1908 (5). But the relation of infantile sexual theories to mythology, as well as certain other matters discussed in his paper, have been omitted here. Let us now proceed to consider the part played by the infantile sexual theories in the composition of the neurosis and the practical bearing of them upon psychoanalytical work. As we know, the infant possesses certain vague impulses, tendencies, and cravings, which, in a general way, represent precursors of the complicated psycho-sexual instinct of the adult (8). When, in the course of development, the child reaches the latency period, and there then appear the inhibitory feelings of shame, disgust, morality, sympathy, etc., the process of repression sets in, and a varying proportion of the earlier impulses, or psychosexual components, is excluded from consciousness. The neurosis represents a failure of repression, and this failure permits some of the early trends to reexpress themselves in consciousness, and to secure a sort of roundabout gratification in the form of symptoms.
In general, these symptoms represent more or less distorted erotic fantasies serving as wish fulfillment. But these fantasies are usually old ones, i.e., ones which were formed in early childhood, and necessarily, therefore, they are based upon the infantile conception of sexual activities. In other words, the neurotic falls sick in terms of infantile rather than of adult sexuality; his symptoms are shaped not by the experiences held in childhood, rather than with regard to the better knowledge of later life. It is upon this account that a knowledge of our patients' early conceptions of sex is of prime importance. Without such knowledge the psychological structure of many neurotic symptoms would remain a mystery to us, and the analytical cure of these symptoms would be an absolute impossibility. The brief case reports that will now follow, I hope may illustrate these points satisfactorily.

**Case I.** The patient was a man about twenty-three years old. His symptoms consisted chiefly of compulsive ideas relative to masturbation. He feared that a rather free indulgence in this practice as a boy had injured him sexually and that, as a consequence of such injury, his voice was high and peculiar, his genitals smaller than normal, and his reproductive power impaired to such a degree that it would be impossible for him to marry or to have intercourse. In other words, he feared that he was extremely effeminate. These fears came on a few months after he became engaged to a young woman, and had existed more than three years before I first saw him. But though from the first he worried over his condition considerably, he did not tell of it, nor was he really very sick, until some four months before I first saw him. At that time they had grown worse. Though previously he had been able to laugh at his obsessive fears, they now became almost delusions. He sometimes fancied that other people noticed his condition and that women were probably as much afraid of his unbridled sexuality. He gave up his work, became greatly depressed, cried a great deal, and wrote to his fiancée telling her that he was impotent and that their marriage would be impossible. He consulted a number of physicians who assured him there was nothing wrong with him, but neither the state-ments nor a course of Christian Science which he under-went brought him the slightest relief. When he came to me I undertook an analysis of the case, and will now relate some of the facts brought out. When the patient was about one year old he had a thorough examination and was taught by him to masturbate. This practice he continued until he was about sixteen years of age. Between his eighth and twelfth years, he and some other boys engaged rather frequently in mutual masturbation and pederasty. The latter act impressed him so favorably that, as a little boy, he often thought there was no particular need of marrying a woman, for, in his opinion, a boy would do as well. When about thirteen he heard about hermaphrodites and, as he said, "wished either to know one or to be one." Though there were practically no gross sexual experiences with females in his childhood, he was, however, anything but indifferent to the opposite sex. He had a great desire to see naked various girls and women of his acquaintance. And, even up to his eleventh or twelfth year, he had many highly colored erotic fancies concerning some of his female relatives. In his relations with his father he showed the mixture of fear and love and repulsion not unfrequent. Though throughout his childhood he was unusually active sexually and no true latency period was established, yet, from the time of puberty up to his engagement period, he rather tended in the opposite direction. During his whole life he made a number of attempts at copulation. At none of these attempts was he successful, for, though he had no difficulty in getting an erection, emission each time occurred before his penis entered the vagina. He negated the idea of homosexuality in his younger days, always gave him an erection and sometimes resulted in involuntary seminal ejaculation. Without going any further at this point into the personal history of the patient I may say that, as already indicated, the analysis showed that in the direction of both homosexuality and heterosexual his early psychosocial life was very intense. Both this history and the following analysis of a fragment of one of his dreams, one may gain some insight into the meaning of his symptoms.

In his dream he imagined that he met his fiance who, instead of appearing as she ordinarily would, seemed to be a negro. In this dream he asked her: "What does it mean that you are a negro?" and his associations were as follows: "I think of their lack of morality. There's nothing they can't do. They have no scruples. After a few moments his pause continued: 'I've always been interested in the original meanings of words. The word 'scruple' comes from the Latin *scrupulus*, a sharp little stone. To have scruples really means to have sharp little stones.' I saw the significance of these associations immediately, but did not interrupt the patient. He continued: 'Thinking of negroes now brings to my mind something that happened when I was about five or six years old. I was playing with a little negro girl of about my own age and I wanted to see her penis. She was not unwilling that I should, so I tried to pull it out and lifted her clothes. She giggled a good deal and did not give me a very good look at her privates, and, as a result, I received the impression that she had a very small, wrinkly penis of a dried up and crumpled appearance. It did not occur to me that this difference between her organs and mine was due to her being a girl. I thought she was different because she was a negro. I knew that negroes had hard luck in so many things that I thought it not at all surprising that they should be unfortunate in regard to the penis also. A year or two later I happened to be in my mother's room while she was sitting on a chamber vessel. I began to wonder why women had to sit down to urinate instead of standing up as men do. It then suddenly ocurred to me that the reason for this must be that women had much smaller penises than men.'

The foregoing history and the associations to this dream are enough, I think, to bring out the points I wish to make in the case. It is perfectly evident that as a small boy this patient had the theory that normally the penis is possessed by members of both sexes (there were no girls in the immediate family). It is also evident that he clung to this theory in spite of the contrary evidence furnished by his examination of the little negro. Even when he made the important observation that women had to sit down to urinate he missed the correct conclusion, and, instead of guessing the truth and abandoning the penis theory, he merely modified this theory to fit the facts at his command by adding, not that women had no penises, but that they had small ones. It is clear, therefore, that in his earlier erotic imaginations all females must have been represented as equipped with a penis, and that any fantasy of heterosexual activities must have been shaped according to this conception of female anatomy. From this it necessarily follows that his early conception of the ideal female corresponded more nearly to an effeminate male than to a normal female; that any wish he may have had for sexual relations with a female was really a wish for activities more nearly resembling those of invertes than of normal males. On this account it is not at all surprising that he was easily led into homosexual practices and that he found them all too satisfactory. The effect of these homosexual activities was to reinforce the penis theory in directing the patient's libido toward penis bearing individuals. Hence, when he did learn that females possessed not a penis, but a vagina, this in-
formation tended to diminish rather than to increase his interest in the opposite sex, and served to strengthen his already formed homosexual complex.

A fairly complete repression of this complex took place about the time of puberty or shortly thereafter, and this repression remained successful until after the patient became engaged. The neurosis which then broke out represents a return of the homosexual tendencies to consciousness in its disguised form of obsessions. I shall not attempt to discuss the outer circumstances which were the exciting causes of the neurosis, further than to say that various matters connected with the engagement had served to arouse considerable hostility on the part of the patient toward his father, while another series of circumstances had caused similar, but partially repressed, sentiments to exist toward the young lady. In other words, the patient was not altogether satisfied with his love choice, and, without fully realizing it, was of two minds as to the desirability of marriage. The hostile conception of the young lady we expressed in the patient's dream. She is there represented as a negress, and, as shown in his associations, this means that the patient thinks of her as being like the little negro girl of his childhood, i.e., her "penis" is "dried up and crumpled"; she has no "scruples," no "little stones" or testicles.

The fact that the young woman lacked these anatomical structures, which in the patient's sub-consciousness were regarded as the sine qua non of the sexual object, was, without doubt, one of the important reasons for his deferring his marriage by falling sick. One might say that there existed in his sub-consciousness the thought, "We cannot make a satisfactory match, for one penis is lacking." But to this there were added thoughts about castration as a punishment for masturbation and for certain fantasies of a highly objectionable sort, so that there came to his consciousness only the idea, "It must be my genitals that are defective." This obsessive idea also corresponds to homosexual fancies in which he takes the part of the female, and, again, it represents an attempt to correct his hostility toward his father. ("If I were a girl I would get along better with my father"—"girl" is equivalent to having a small penis or no penis.)

At one time the patient had heard of using scrums for various illnesses, and this led him to conceive the idea that if he were to receive an injection of an emulsion of testicles he would get well and be able to have children. This idea, though by no means entirely illogical, bore all the earmarks of an obsessive craving, and concealed a homosexual fancy of receiving the semen of another male. It also represents an effort to compensate for one of the supposed defects of the patient's father. Certain things had given him the opinion that his father would be unable to bear children. The emulsion scheme, then, presents the comforting thought, "If she can't bear children perhaps I can," a thing which was conceived of as one of the infantile sexual theories. It represents the attempt and interpretation of the case which I have given of course represents only a very small part of the analysis. Though a complete report might be of interest, I shall not attempt it, as it would have no further bearing upon the subject in hand.

Case II. Though this history does not concern a sick person, it may, however, be of interest. A normal young man had a marked dislike of small children,—the younger the child the greater the dislike. In their presence he invariably felt embarrassment and a sort of disgust, while they thought of any physical contact with them was very disagreeable.

An attempt to analyze this peculiarity promptly brought out various associations concerning the lack of sphincter control found among infants and the possibility of their soiling any person who handled or held them. This was, no doubt, a partial explanation of the trouble, but a deeper origin became evident when it was discovered that in his early years this individual possessed a well developed interest in the processes and products of excretion. He had formed the "birth by rectum theory," and, therefore, a small baby was to him an analogue to feces, since, according to that hypothesis, they both came from the same place. The symptom, if it may be so called, represents an over-compensation for his long repressed coprophilic interest. The early curiosity about such matters had been replaced in consciousness by the reactionary feeling of disgust, and this reaction was awakened not only by dejecta but by analogous objects, such as a baby, however clean it might be. Following this explanation the symptoms disappeared.

Case III. In April, 1911, I read before this society a paper consisting of the analysis of the following case (6):

A young unmarried woman had suffered for four years from depression of somatic and sexual symptoms, which was an imperative desire to make herself sick either by taking drugs, or by contracting typhoid. The only conscious explanation which the patient could give for these peculiar cravings was that she felt if she could become sick, she would almost certainly then recover, she would be entirely free from all her troubles. Why she had this strange belief she could not say.

In my analysis I explained her desire to be sick as a symptom depending mainly on a strong masochistic complex. Her preference to typhoid over other illnesses appeared to be based upon her knowledge that if, as occasionally happens, an attack of typhoid causes the patient's hair to fall out, the hair may then grow in again of a new color. The typhoid complication really consisted in the wish to have hair of a different color (blonde), but this wish was merely a surrogate for a repressed desire to be in the place of a certain blonde rival. The result of my analysis was very satisfactory, for, from its close in February, 1911, until December, 1911, the patient remained in perfect health. But she then returned to me with the report that for a week or ten days she had been subject to depression and the old desire to make herself sick with drugs had to some extent returned. To this high, I am indebted for the opportunity to complete my analysis by discovering a still deeper determinant for this symptom. This required only two hours, and the patient has been entirely well ever since. That she herself had a certain understanding of the meaning of her symptom was disclosed by her exclamations, almost as soon as she entered
my office: "I know what made the trouble! It was those infernal babies!" She had been called upon to take entire charge of them on account of the unexpected illness of their mother. This work she considered no hardship, however, for she was extremely fond of children and took great delight in caring for them. But the experience soon awoke her natural desire to have children of her own to such a degree as to be almost a torment. She then became depressed, her old desire to make herself sick returned, and she took to drink so far that on four occasions she took large doses of aromatic spirits of ammonia and, at another time, headache powders.

In view of all these circumstances I could quite agree with the patient that contact with children had caused the return of her compulsion. And since the symptom returned at a time when her desire to have children was strongly aroused, I concluded that it must represent, symbolically, a fulfillment of that desire. Having reached this conclusion, I found the rest of the analysis very simple. As a child the patient had not failed to see a correlation between certain seemingly serious illnesses of her mother and the coincident arrival of a small brother or sister. After having realized this connection she then began to wonder what caused the malady having such remarkable sequelae. She finally concluded that her mother had made herself sick by taking some peculiar sort of medicine furnished by the druggist. But, if the mother could get babies in that way, so could the child; all she needed was the proper drug. It was this long forgotten theory that was at the bottom of the sickness compulsion—the taking of drugs represented insemination; the resulting illness meant pregnancy. When, after puberty, the patient learned of the existence of the spermatozoa (which she looked upon as "germs"), this new knowledge was assimilated with the old, and thus germ diseases became symbolic of pregnancy. Typhoid is a particularly good symbol since, as the patient was aware, it may be contracted by kissing, and hence, it is a symptom. (Its other significance we have spoken of already.) The patient's peculiar idea, before mentioned, that a serious illness would make her well, we can now interpret as, "If I had a baby I would be perfectly happy."

BIBLIOGRAPHY:

I WEST EIGHTY-THIRD STREET.

OCULAR VERTIGO.

By Aaron Brav, M. D.,
Philadelphia.

Ophthalmologist to the Lebanon Hospital.

By ocular vertigo we mean that condition in which the sense of equilibrium is temporarily disturbed, so as to make objects that are ordinarily fixed in space appear to move in a wheellike fashion, and which is caused by some ocular disturbance. To have actual vertigo (not an ordinary dizziness) there must be a disturbance of objective as well as subjective orientation, which interferes with our sense of security in space.

Normally, we have acquired the sense of appreciation of the relationship of objects in space to one another, and we are able to ascribe them to the place they actually belong, by means of the law of projection of the retinal image outward. This is known as objective orientation, and depends upon a purely physical basis, upon the place of the retinal image, that is, its relation to the fovea centralis. This, however, would be insufficient to establish our sense of security in space. In order to possess perfect physical poise, or the sense of security, we must also have a definite relation of our body in space and the relationship of our body to objects that surround us. This knowledge we obtain from the muscular sense of our extrinsic and intrinsic ocular muscles in their state of activity. This we call subjective orientation. Thus our sense of security in space depends largely (if not altogether) upon the knowledge of the relationship of objects to one another and the relationship of our own body to the objects surrounding us.

The sense of security in space is probably a psychic problem, but, like all other psychic phenomena, it depends upon a physical sensation. Appreciation of light, recognition of form, perception of depth, determination of dimensions—all these complicated psychic phenomena are probably essential to our sense of security in space. Our position in space necessarily depends upon our visiomuscular apparatus. It may be conjectured that all vertigo, or vertiginous spells, are the direct result of some ocular disturbance. although the ocular disturbance may not be a primary condition, but a secondary phenomenon (perhaps temporary) caused by some organic or functional disturbance, or some toxic substance elsewhere in the body that directly or indirectly acts upon the muscular or accommodative apparatus of the eye. The semicircular canals, if they play any part in our sense of security in space, are only accessory elements, but not prismatic factors. The chief causal element of vertigo, therefore, must be found in a disturbance of our oculomotor apparatus. Delusion of space, of depth, of distance, of dimension may under certain circumstances temporarily destroy our relation to objects that surround us, interfere with our power of fixation, unbalance our equilibrium, disturb our objective and subjective orientation, and give rise to vertigo.

CAUSES OF OCULAR VERTIGO.

The causes of ocular vertigo may be tabulated in the following way:

(a) Paralysis of the external ocular muscles.
(b) Spasm of the external ocular muscles.
(Simple. Compound. Mixed.
3. Accommodative. Paresis of the ciliary muscles.
4. Disturbed relation between accommodation and convergence.
DISTURBANCE OF MOTILITY.

It is a known fact that the external ocular muscles play an important part in subjective orientation. Binocular single vision necessitates binocular proper fixation. In order to appreciate binocular single vision, the objects sighted must be fixed so that rays emanating from it shall fall upon a definite point on the retina, to wit, the fovea centralis. This can only be accomplished by the harmonious activity of the external ocular muscles. If these muscles by reason of paralysis or spasm do not act conjointly, binocular fixation is either difficult or altogether impossible, depending entirely upon the degree of the muscular deviation. When binocular single vision is entirely impossible because of faulty fixation, the result is a diplopia which causes a confusion in the perception and a disturbance in the equilibrium, which in turn gives rise to vertigo. This is often observed in cases of paralysis of some of the extrinsic muscles of the eye, especially when our attention is drawn in the direction of the paralyzed muscle. Usually the man with a paralyzed extrinsic muscle of the eye learns to compensate for the failure of muscular strength by posture of the head, or overcomes the diplopia by closing one eye. When these compensatory efforts are not employed and diplopia is present vertigo may be the result.

Any attempt to overcome the muscular deficiency by an increase in nerve force only complicates matters, for the excessive nerve force not being able to influence the paralyzed muscle increases the activity of the antagonistic or associated muscles, enlarging the angle of deviation. The false projection resulting from a paralytic condition of the extrinsic ocular muscles must be considered a cause of the diplopia and the vertigo. But vertigo may be present even without diplopia. To avoid double vision one only has to close one eye, no matter which one is closed, but to avoid vertigo one must close the paralyzed eye and fix with the normal eye. When the paralyzed eye is used for fixation (the good eye being excluded) there is no diplopia, but vertigo may still result. The attempt to fix an object with the paralyzed eye in the direction of the paralyzed muscle is not infrequently followed by sudden apparent movements of objects around us, and this causes the vertigo. Thus vertigo from paralysis of the extrinsic ocular muscles may be excited in two ways, first, by the diplopia, and secondly, by an effort at fixation with the paralyzed eye in the direction of the normal action of the paralyzed muscles.

Partial paralysis or paresis of an ocular muscle, may, of course, also give rise to vertigo. Paralysis of the extrinsic ocular muscles is usually caused by some constitutional disease, such as syphilis, diabetes, nephritis, rheumatism, tumors of the brain, etc., which the ophthalmologist must bear in mind, so that the ocular vertigo of this type is primarily of constitutional origin.

SPASM OF EXTERNAL OCULAR MUSCLES.

Temporary spasmodic contractions of the ocular muscles, may also give rise to vertigo. Practically the same conditions prevail here as in a paralytic case. We have the deviation of the fixation point in some direction, that is, in the normal direction of the spasmodic muscle. We have a manifest or a latent diplopia and above all we have false projection. Patients with spasmodic conditions of the ocular muscle in reaching out for an object will invariably undershoot the mark. The patient usually underestimates the distance that the eye travels, because of the overacting muscle that requires less effort than is normally required. As a result of this underestimation, or delusion of distance, an apparent movement of objects looked at may be produced and thus produce vertigo. Vertigo may be produced by the diplopia, and the apparent movement of objects as a result of false projection. When the spasm is permanent and results in contracture of the muscle there is no more diplopia present, for one eye has been excluded entirely from the act of vision. Even the false projection has been overcome by a reeducation of the muscular sense. In these cases vertigo is rare. Permanent spastic conditions of one of the ocular muscles may be observed in long standing cases of paralysis of the ocular muscle where the antagonistic muscles become contracted secondarily. As a matter of fact, probably all cases of spasm of the extrinsic muscles are secondary to some paresis; primary spasms of the ocular muscles is rare, although it may be observed in irritative conditions of the brain, in meningitis, or in reflex action from some dental irritation.

DISTURBANCE OF ACCOMMODATION.

Vertigo results not only from disturbances of the extrinsic ocular muscles, but may also result from a disturbance of the intrinsic ocular muscles, especially in cases of spasm of accommodation. Spasm of the ciliary muscles gives rise to a chain of symptoms among which vertigo is not uncommon.

Spasm of accommodation causes changes in the refractive status of the eye, reducing it considerably. It may convert an emmetropic or even a hypermetropic eye into a myopic, which fact can easily be determined by the instillation of atropine. It will give rise to macropsia, where objects will appear larger. It may also produce an irregular astigmatism, with difficulty of fusing images, that will result in a latent diplopia, or an overlapping of images. Delusion of space, distance, and size may result from ciliary spasm, giving rise to headache, dizziness, and vertigo. Vertigo results mostly when the spasm is not of a tonic, but rather of a clonic nature. When the period of relaxation is followed again by a spasmodic contraction of ciliary muscles, vertigo may be present, for the difference in the refractive status of the eye may cause a confusion, with a temporarily apparent movement of objects that surround us and thus produce vertigo.

Paralysis of the accommodation rarely, if ever, produces vertigo unless it is also complicated with paresis of one of the branches of the third nerve. I have never observed vertigo as a result of a simple paralysis of accommodation, but have seen several cases of vertigo as a symptomatic expression of the spasm of the ciliary muscles. There is usually a constitutional condition underlying the spasm of the ciliary muscles, and in treating these conditions one must bear in mind the constitutional aspect as an etiological factor. The disturbed relation between accommodation and convergence must also be borne
in mind. This will be discussed under a special heading.

REFRACTIVE ERRORS.

Errors of refraction are often responsible for a chain of symptoms as a result of eye strain. Vertigo not infrequently is one of the symptomatic expressions of asthenopia. Among the various forms of refractive errors, it is the astigmatic type that usually is of etiological moment. Astigmatism simple, compound, hyperopic, myopic, or mixed, all may give rise to vertigo.

There are at least two ways in which astigmatism may give rise to vertigo. First, as a result of the accommodative effort of the ciliary muscles. It must be remembered that in many forms of astigmatism objects appear somewhat distorted, and also elongated. The astigmatic cannot see all lines distinctly. He can only appreciate, for instance, part of letter, but he learns often to interpret the whole letter by the part he sees distinctly. In some forms of astigmatism, especially where there exists an anesometropia (an unequal refraction in the two eyes), there is probably a latent diplopia, caused by the unequal refractive status of the eyes, which produces images of different sizes in the two eyes. This delusion of size the ciliary muscles try to overcome. There is thus an unconscious effort of an unequal attempt at accommodation, which only increases the difficulty, causing a confusion, and a disturbance in the equilibrium, resulting in vertigo. Secondly, through the efforts of the external ocular muscles. During the attempt at accommodation to overcome the astigmatic aberration there is a simultaneous corresponding attempt at convergence. These two causes combine to interfere with proper fixation, which interference gives rise to vertigo. According to Duane (Fuchs, p. 781) objects appear in apparent motion, wheel-like figures appearing to revolve and check patterns seeming to dance. This causes asthenopia and vertigo. Every ophthalmologist has some such cases on record. I have several cases of vertigo on record caused by astigmatism which had given a chain of symptoms simulating brain tumor. I have also observed double vision as a result of astigmatism, which of course may produce diplopia.

DISTURBED RELATION BETWEEN ACCOMMODATION AND CONVERGENCE.

Probably all cases of ocular vertigo are to be attributed to some disturbance of motility, regardless of the primary cause of the disturbance. The primary etiological factor may be a toxemia from some constitutional disease, an error of refraction, or a disturbance in the accommodation, which acts on the motor apparatus of the eye, producing a temporarily active or latent diplopia. Proper fixation is essential for the maintenance of a balanced equilibrium. Anything that interferes with perfect fixation may occasionally give rise to vertigo. An apparent movement of objects round us is observed in rapid locomotion, as on a railway train, where perfect fixation as a result of speed is not possible. There is a well established relation between fixation and accommodation, as well as pupillary reaction. While to some extent an independence of these two motor functions may occasionally be noticed, and may even be artificially produced, yet no one can disprove the fact that there exists to a large extent an association of the two phenomena. Whenever a marked disturbance between the two functions is present, there is an interference in fixation, and objects appear to move in space. A sudden effort at accommodation, say, to overcome some difficult refractive error accompanied by a simultaneous jerky movement of the external ocular muscles, in cases where there is an abnormal relation between the activity of the intrinsic and extrinsic ocular muscles, may cause objects to appear to move about. This may be noticed where a sudden jerky movement of the head and neck produces the same condition. I have often observed this condition in myself, and explained it on the ground that the action of the external ocular muscles was not able to focus during the rapid movement of the head.

Axiomatically, one may say with sufficient amount of certainty that ocular vertigo, whether due to astigmatism, paralysis of the extrinsic muscles, or accommodative difficulties, is the direct result of the disturbed relation between the ciliary muscles and the external motor muscles of the eye. This disturbed relation gives rise to false projection, improper fixation, interference with orientation, active or latent diplopia, unequal retinal images, difficulties in fusing images, delusion in space, size, depth, and dimension, disturbed equilibrium and an apparent movement of objects in space, and subsequently vertigo.

INHIBITORY OCULOMOTOR CENTRE.

In considering the relation of accommodation and convergence, one is, of course, confronted with the fact that it is possible to accommodate one or two diptres without any visible effect of convergence. Thus, for instance, in fixing a near point where the eyes converge to a certain angle, and then placing a minus two lens before the eyes, there will be a temporary blurring of the object fixed, which, however, will soon be overcome by the effort of accommodation, the eye remaining fixed at the same angle. This may be explained, however, by the assumption of the presence of an inhibitory centre, regulating the relation of the accommodation to convergence whenever it becomes necessary to accommodate without a corresponding convergence. Experimentally, one cannot demonstrate the existence of such a centre, but clinically I assume this to be correct and possible. The human eye is thus provided with an association centre for accommodation and convergence, as well as an inhibitory centre for accommodation without convergence. Convergence without accommodation is not very probable. It is true that in old age the act of convergence is not accompanied by any accommodative results, but this is because the ciliary muscles no longer respond to the nerve impulse, so that even in old age the act of convergence gives rise to a simultaneous stimulus for accommodation; but the muscles, no longer able to respond to the impulse, do not produce any visible result.

Ocular vertigo in the aged, where the accommodation is at absolute rest, is due to an interference with fixation, delusion of size and distance, differ-
ences in the retinal images of the two eyes, but not as a result of accommodative effort, except, perhaps, in this way. The presbyope may attempt to accommodate, but the ciliary muscles do not respond to his will, for they are not able to change the curvature of the lens, while the extraocular muscles through the association centre governing the relation between accommodation and convergence do respond quickly to this extra nerve impulse, and this strong effort at accommodation by the ciliary muscles that no longer respond produces a quick response and an overaction of the extrinsic ocular muscles which may cause an apparent movement of objects and vertigo.

917 Spruce Street.

VINCOLA PRETERITORUM.

By William P. Cunningham, M. D., New York,

Clinical Lecturer on Dermatology at Fordham University; Assistant Physician at the Harlem Hospital, Dermatological Department; Clinical Assistant at the New York Skin and Cancer Hospital.

The sage injunction, "Let the dead past bury its dead," is no more heeded by the doctors than the lawyers. The latter, obviously, in the absence of a past would have no future, for all the snaky twists, turns, intricacies, and interlusions of their bewildering ratiocinations are absolutely dependent upon precedent. It is their purpose and business to make the present conform to the past. The fate of John Smith to-day is determined by the fate of that other John Smith at the hands of some English judge three hundred years ago. Precedent is the supreme arbiter of justice. So for the lawyers there is no dead past, and there is no dead for it to bury. For them the past is vital. It is the storehouse of their energy. It is the magazine of all their fulminations. But why should medicine, ever seeking, ever striving to improve the health of man, suffer itself to be ruled from the grave, in stupid deference to precedent? It will be objected that this condition does not exist, as demonstrated by the tremendous advances made in surgery and bacteriology within a double decade. What did our forbears know of laparotomy? What hint had they of the tubercle bacillus and the Spirochete pallida? In their most vain imaginings, did they ever soar to an x ray, a Wassermann reaction, to a diphtheria antitoxine, or a vaccine against typhoid fever? All these marvels exist to-day, and yet we are guilty of the absurd declaration that this magnificently progressive science is bound up with the dead past! Is hampered and o'erswayed by precedent? On cahn investigation this glaring absurdity is seen to be only apparent. Along some special lines great strides have been taken. Even in the law the same thing has occurred. The "Question" is no longer put through the medium of the thumbscrews, the "boot" and the rack. Within the confines of civilization, imprisonment for debt, honestly contracted, is no longer tolerated. Trivial offenses are no longer punished by hanging. State religions and the court, to quote our old friend Barks, "have been put in smiths" and men are no longer burned for heresy. But, despite these admittedly great reformation it is nevertheless undeniable and undeniable, that the lawyers cling to and build upon precedent to the exclusion of almost every other consideration. It is the "habit" of mind that is at fault. Let us who boast of our wonderful secession from the past and our dizzy flight into the empyrean of progressive science, examine our pretentions candidly and determine if we have outstripped the lawyers who admit the dominance of precedent. It is a glorious achievement to have saved thousands of lives from the ravages of diphtheria; is it not something to have rescued thousands from the stake? Will not the abolition of legal torture compare favorably with the discovery of anesthesia? Will not the principle of arbitration, preventing war, do as much for the preservation of human life as the antityphoid vaccination of the fighting man? What is the ultimate economic difference between his succumbing to the typhoid bacillus or the bullets of the enemy? Has not the abolition of indiscriminate hanging contributed to the lengthening of the term of life quite as effectually as the scientific percentage feeding of infants? It were economic waste to save the infant for the hangman. The point is made, and we hope sustained, that changes in the method of administering justice have contributed to the health and longevity of the people in a manner comparing very favorably with the changes in the practice of medicine. Yet the legal fraternity frankly admit their dependence on the past, whereas the medical fraternity, just as tightly bound by habit of thought, vinulns preteritorum, vaingloriously proclaim their emancipation therefrom, and the setting of their faces toward the rising of the sun.

We have discovered the pneumococcus; have we discovered any way of limiting its activity? In the treatment of pneumonia, what is the dominant practice to-day? By the extreme antiquarians the external application of heat; by the neantiquarians the external application of cold; by both, stimulation. The same old ingrained idea of limiting the progress of the disease by stimulating or inhibiting the cutaneous nerves in its vicinity.

We have discovered the tubercle bacillus; have we discovered any way to destroy it in the living subject? Or, do we rely as of yore upon the restraining influence of ozone and supernutrition?

We have discovered the gonococcus; have we discovered any infallible method of combating its ravages? We have argyrol instead of silver nitrate. We have the urethroscope to locate persistent patches of granulation. And we have the same old gonorrhea running about the same old course, and we give the same old balsams, just as our remote ancestors did.

It is not my purpose to multiply illustrations drawn from the general practice of medicine, although the temptation is great and the opportunities limitless; I wish more particularly to point the moral in the narrower but more familiar field of dermatology.

In another place I have tried to show that dermatology is a most important aid to the physician in the diagnosis of systemic disorders. In depredating now our adhesion to antiquated ideas and methods of treatment, I have no notion of minimizing the truth of that contention. Dermatologists, let
us see in what conspicuous particulars we have distanced our predecessors. We have the lepra bacillus, it is true, and we still have leprosy. We have the Bacillus anthracis, and still have anthrax. We have the streptococcus and still have erysipelas and, except in the case of the last mentioned, the management of these diseases has not been altered by the identification of the cause. Coley's fluid is occasionally used with good results, but is usually ignored. But what of eczema, what of psoriasis, what of the lichens, what of dermatitis exfoliativa, what of dermatitis herpetiformis, what of ichthyosis, what of plain, ordinary, plebeian urticaria? Except in some distinctions as to type, what has been accomplished in the elucidation of these affections? What single thing do we know of the etiology of psoriasis more than our quite remote ancestors? And in its treatment, how slavishly we adhere to their methods of procedure!

Twenty-five years ago, Edward L. Keyes declared that the treatment of eczema resolved itself into the application of zinc to acute and tar to chronic cases. Has there been any material alteration during this quarter of a century? Of its etiology nothing was known then and nothing is known now. Why there should be the determination of a vesicular dermatitis to one man's skin and not to another's, when both were subjected to the same influences, is a mystery to which we have absolutely no clue. Surmise is rife, but evidence is coy. Relative power of resistance is the favorite refuge of those who do not like to admit their ignorance of the cause. We leave you to decide what that may mean. To us it simply means that one man gets it and another does not. With our faces turned squarely to the past, we go right on plastering the patients with messy salves, which sometimes suppress but do not cure the disease, flushing the bowels with nauseous cathartics, thus lending temporary aid to struggling nature in the labor of elimination; and compound ing dietaries that are frequently haphazard shots at the cause that we cannot define. What solitary idea has been advanced, within the memory of the oldest practitioner, which has illuminated in the slightest degree the etiology of eczema? En pas sant, it may be postulated that there is the glimmering of a discovery in the suggestion that the nervous system having control of all the trophic elements is logically responsible for all the dyscrasias. It is conceded that an exciting cause is always at work in the production of an eczema. This may be within reach of our eyes and remediable. Or it may be beyond our ken and irremediable. Whatever that cause may be it operates through its influence on the trophic nerves. How it does so we are at present utterly unable to understand. Why it operates on one series of exposed individuals and not on another is equally inexplicable. Yet it would seem to be along that line of investigation that illumination must ultimately come. Instead, however, of bending all our energies in this direction we are as busy as beavers doing the palliative things originated in the hazy conceptions of our ancestors.

Dermatitis herpetiformis described by Duhring, and ascribed to some aberration of the nervous system, has not had one scintilla of light shed upon it since its famous author rescued it from the confusion of the eczemas. What pathological factor so disturbs the function of the nerves as to bring into existence the lesions of this torturing disease? Here we are brought up standing. We have no answer to the question. The differentiation of the various factors operating through the nervous system for the production of eczema, dermatitis herpetiformis, urticaria, erythema multiforme, et al. is, a fortiori, utterly impossible. Therapeutically we plaster and palliate, with inherited persistence.

In acne and furunculosis a distinct departure has been achieved in the production of an effective vaccine. This only serves to emphasize our dull adhesion to ancient usage in so many other conditions. We raise a tremendous fanfare of selffla dation over the "discovery" of the poisons generated in the pestilent intestinal tract, and feverishly attribute thereto the causation of all our nosological puzzles, from shingles to senility. We prate incessantly of skatol, indoxyl, and indol, as though the separating and labeling of these egregious malefactors had disposed of the whole problem of autointoxication. In the midst of our swelling pride let us not forget, that with the single exception of the cacophonous titles, the whole proposition was perfectly understood. ex omni seculorum memoria. Purging has been the commonest therapeutic resource of which we have any information. The ancients had no knowledge of bacteria or of the definite noxions reactions occurring in a disordered intestine, but they had a perfectly clear appreciation of its pathogenic influence on the human organism and of the necessity of sweeping it clean of all offending materials. So as an antidote to our overwhelming selfcomplacency, let us consider that in this particular nosological connection we are looking backward with a vengeance. Likewise in regard to the "latest" treatment of intestinal putrefaction, namely the administration of the lactic acid bacillus, we are harking back to a custom of the Bulgars running through the centuries. They are a people of unusual robustness and longevity and their vitality is attributed to drinking sour milk. Perhaps they could not describe the modus operandi of their panacea; probably they would be amazed to learn that we harbor within us such pests as skatol, indol, and indoxyl; but they had come, by accident, most likely, into possession of a great truth, which we have greedily appropriated, with many flourishes at our own astuteness. Let us tarry for a moment over plain ordinary urticaria. It is probable that we treat it in about the same way as did the ancient Assyrians, by cutting out meretricious pabula and eliminating that already ingested. Yet the pretty problem of the production of the wheal is as great a mystery to us as it must have been to them. Why should the particular dietary indiscretion (indulgence in crabs, lobster, pork, veal, strawberries, bananas, et al.) precipitate an angioneurosis resulting in the sudden dilatation of the vessels in one or several sharply circumscribed localities, with solid effusion into the lymph spaces? What sort of toxine attacks the nerves, and what determines the selection of particular nerves? Furthermore, what determines the
production of papules in some instances, and vesicles or bulke in others. What answer have we to these questions? None. Frankly we know about as much on this subject as any of the peoples of antiquity whom we might select for purposes of comparison. With so much to arouse our scientific interest we go on dully oblivious of our opportunity, and supinely subservient to precedent.

Erythema multiforme is an analogous condition, with the exhibition of lesions similar to those just described, but differing from urticaria in the absence of itching. What determines the toxine to omit the itching? What determines it to form a papule with a central depression? Illustrations might be cited at very much greater length, but *sufficit diei malum ejus.* It has been shown that with us doctors the dead past has not buried its dead.

Not one word of disparagement is intended for those indefatigable souls that have fought their way into the future against the pressure of the custom ridden past. We grant them full meed of praise. We exempt them from the indictment found against our fraternity, for inertia, plagiarism, and a spineless surrender to inherited misconceptions. If we could be brought as a class to emulate the example of these illustrious pioneers, we would quickly emerge from the slough of confusion on to the firm ground of scientific precision. If every time we see a case of eczema, instead of yielding to the atavistic impulse to besmear him with variously offensive ointments, we should strive to discover the cause of his disorder and the manner in which it acts through his impressionable nervous system, we should soon begin to make progress of a substantial character. But not we! If one salve does not serve we try another. If that fails we try a third and we keep up a blind groping for a possible hit in the dark with a perverse persistence limited only by the patient's endurance. After we have exhausted the expedients of one authority we rush to another. Poorly enunciated, he makes another essay, another, and another, always looking backward and never for a moment seeking within ourselves the explanation of the pathological phenomenon we are confronting. Exactly like the lawyers, we rely upon "decisions" which are usually compilation of previous decisions. What does Hebra say? What does Unna say? What does Sabouraud say? What is Kaposi's opinion? What does Crocker suggest? What is the attitude of Stelwagon, Montgomery, Hyde, Jackson, Walker, and the others who have collected the opinions in vogue at the time in which they wrote, and set them before us as the law in all cases made and provided.

As an illustration of how this reverence for the "authorities" devitalizes the practice of medicine let us consider for a moment varicose ulcer of the leg. If a physician had read nothing about this condition and had to use his wits to find a remedy, he would quickly reach the conclusion that, venous circulation being faulty and arterial circulation increased by motion of the limb (thereby still further overtaxing the englutted veins), the logical remedy would be to support the veins and reduce the arterial circulation. He would note that the whole proposition was one of physics. If practicable he would put the patient to bed and apply a bandage from the toes to the knee. In any event he would apply the bandage and thus effect at least half his purpose. But having been educated with a profound reverence for the "authorities," he immediately turns to them for guidance, with the result that he is impressed with the particular efficacy of some local application, and loses sight of the main element of treatment. This application failing, he tries another "authority" and another salve. Nothing daunted by his second ill success, he continues his reverential quest, and the patient enters on his long pilgrimage to the different temples of Aesculapius. We have all seen them; we have all had them to treat, great thickened fibrous excavations, at this stage resisting every effort at restoration. Watch the routine management of these cases in the dispensaries. Observe the constant procession of salves, the senseless therapy of the surface when the depths are "out of joint." Note the slovenly bandaging, with no pretense of accomplishing anything but the retention of an impotent ointment.

Time and again, I have seen the nurses start a bandage at the ankle, run it to the knee, and tie it in the middle of the leg! Time and again I have seen the clinician direct a change of treatment and ignore this technical monstrosity.

Had his mind been on the right track, he would have seen that what he put under the bandage was of little consequence compared with the proper application of the bandage itself.

Many years ago Beverly Robinson told his class, of which I was one, that he could exhaust all he knew in two hours' talk on the throat and nose. Yet he had written a large book upon the subject because it was necessary to incorporate it all that "Tom said, and Dick said, and Harry said." That is the crux of the whole proposition. "What Tom, Dick, and Harry said" must be reheashed even if the author disagrees with them, and their opinions are handed down, and their errors perpetuated, and sanctified by time until the reader is hypnotized by these voices from the grave. Recently I read an article published in the Journal of the American Medical Association on "new" diagnostic criteria of incipient tuberculosis, and (barring the one factor of the x ray) every single solitary idea had been taught by James R. Leaming, who is now dead twenty-five years. What's the odds, you say, if both told the truth? None. But how about our pretense of getting upward and onward, with a retrograde movement like that?

In the same journal of a later issue appeared an article by Ravogli, of Cincinnati, upsetting Colle's and Profeta's law. He establishes the contention that there is no immunity to syphilis except actually existing syphilis; that the mother who brings forth a syphilitic child while she is apparently healthy, and whose infection from the mouth of her blighted nursing, is in reality already infected herself. If Colle's law holds good in so far that the mothers of syphilitic children are not infected by their babies' mouths, and if it is true as Ravogli says that there is no immunity to syphilis except by means of existing syphilis then it follows positively that the mothers of syphilitic children are always infected, and *mirabile dictu* the position of Keyes, enunciated a quarter of a century ago, is
sustained, namely that the father can only transmit the disease to his offspring by previously infecting the mother. Which is another beautiful illustration of sartor resputus, mortus redundis, historia sese repetens, vivus viv et bouteilles nouvelles, second time on earth, or any other familiar formula by which one seeks to convey the impression of an old idea revamped.

Across the world of modern medicine came a trumpet blast of triumph from out the city of the greatest living seropathologist. “Syphilis is cured!” Ehrlich hath said it! One injection of his marvelous discovery and the scourge of civilization is no more! The most tremendous achievement since Jenner stayed the ravages of its reputed congener, the smallpox! A wave of delirious enthusiasm swept o’er the medical fraternity, matched only by that of the carnal voluptuary who welcomed such an easy means of dodging the wages of sin. Throughout the reaches of civilization and especially in our own beloved country a feverish activity to put this marvel to the proof was instantly aroused. Synchronously thousands of expert hands were eagerly at work. Speedily their hopes were verified. Did not lesions melt before this magic golden liquid, like snow before the sun. Banzai! Great is Ehrlich! He has found a means to sterilize the blood of these infected patients. It was reasonably safe at that. There were a few deaths directly traceable to the injections, but these were airily attributed to other causes, and did not dampen the overmastering jubilation. But now bitterer than death itself came whisperings of failure here and there, of relapses hard to be accounted for, if the patient’s blood were sterilized as we had been assured. Faced with this the prophet of the new dispensation declared that some of the spirochetes must have been hidden in the glands and so escaped destruction. He advised more injections to root them out. It was finally decided that four injections constituted the proper dose for their ultimate and complete extinction. There the case might have rested to everybody’s satisfaction, if the pestilent spirochetes would run according to form and drop dead when directed. But obstinate ones persisted in disconcerting resurrection, until it was certain that further measures must be employed. With what wonderful skill and courage did the masterly discoverer meet this emergency! Think of it! Could any one but a genius have devised such a plan! Could any one but a mighty heart have dared to promulgate it! Listen now with bated breath to the pregnant words of wisdom falling from his lips. “Give your four injections of salvarsan, and then put your patient on mercury for two years!” In which direction are we looking now? Forward, or backward? And has this worldwide touting, worldwide patented instantaneous annihilator of Gargantuan lues resolved itself into anything better than a cosmetic or emergency remedy admittedly effective in cleaning up surface manifestations? I know men who use it only because it pays to do so. They say they do not know what will be the ultimate result on brain, and cord, and kidney, and that if they themselves were the victims of lues they would not submit to the administration of salvarsan. Other men are of the opinion that the time consumed in the preliminary salvarsan treatment is a serious detriment to the patient as long as he has to get down to the mercury treatment in the end. These opinions are privately delivered. In public print and lecture they fall in step with the prevailing trend. The only point I seek to make from all this is that after salvarsan comes mercury (for two years or more), and that despite the resounding din of gratulation over this marvelous advance we are still in vinculis præteritorum.

Great and original minds resist the domination of entailed antiquities and accepting what is positive, and doubting what is problematical, press forward in restless quest of scientific certitude. But by the majority new ideas are looked on askance, unless bizarre and reconcite, and advertised with brazen clamor. What should be obvious has to be hammered into our dull comprehension. We oppose the novel, because it does violence to our self esteem, showing wherein we have been remiss; because inertia fights against the labor of leaving the beaten track; and, most especially, because we are shackled by the blighting habit of retrospective inspiration.

Having paid our respects to the past in the preceding manner, let us not forget that it is the fossilization of our mental processes that we decry and not the work performed by our forbears. Mighty intellects have existed in all ages and performed miracles with the opportunities at their command. They made diagnoses, without an x-ray, without a Wassermann, without a lumbar puncture, without a sputum examination, and without a blood count, and made them early and accurately too. Men like Lewis A. Sayre needed no skiaigraph to detect a tuberculous joint. Men like Bumstead and Keyes could demonstrate lues as certainly as the Wassermann. Men like Delafield, Flint, and Learning, by the acuity of their observation and the cogency of their reasoning, were just as brilliant internists as any of the present generation fortified by all the newer methods of precision. Janeway would not falter at a diagnosis of meningitis in the absence of a lumbar puncture. I have seen Joseph E. Winters strike with brilliant accuracy in the tuberculous phase of that dread disease, and seek no laboratory aid. No discredit is sought to be cast on these various methods of confirming diagnosis, but to have them supplant entirely the older and equally effective methods is a distinct step in the wrong direction. Reliance on these “methods of precision” is causing students to disregard the other ways of reaching a conclusion, and the valuable art of diagnosis is retrograding into the hands of the photographer and serologist. We are producing a class of men, who, ceasing to be clinicians, will become brokers for the laboratories.

As an afterword, to obviate any apparent inconsistency in these pages, I beg leave to epitomize in this wise: Along certain lines distinct advances have been made. Along others, especially noticeable in the domain of dermatology, progress has been painfully slow. This is due to the ingrained habit of reverting to the past, and doing things because they were done before. This mental attitude, unfortunately, seizes not only upon the vital and enduring truth, but upon much that is “flat,
stale, and unprofitable.” In many ways in the great problem of the conservation of human life, we have stolen the thunder of our grandfathers and branded it as our very own. In many other ways, we have paralleled their achievements, and because our technic was a little different from theirs we have raised a great shout of admiration at our splendid superiority. In most ways, however, our minds have been ruled and our progress stayed, by the influences emanating from the past. This we in our pride do not often admit, but an impartial consideration of the many errors still accepted by the majority of the profession will convince the vainest that we are still “in vinculis præteritorum.”

317 West Fourteenth Street.

LABORATORY STUDIES OF THE MANIC DEPRESSIVE GROUP.

BY J. ALLEN JACKSON, M. D.,

Philadelphia,

Chief Resident Physician, Philadelphia Hospital for the Insane.

The following examinations were made as a general routine measure of the general admissions to the Central Indiana and Philadelphia Hospitals for the Insane, without any particular object in view other than the findings. I wish to briefly discuss the urinary findings, gastric analyses, examination of the feces, blood examination, blood pressure, and the autopsy findings.

Uranalyses. Over three hundred cases of the urinary findings of the various psychoses have been studied and the most prominent constant finding was indican. This was positive in seventeen per cent. of all the cases examined.

Manic depressive group: Twenty-four per cent. of the total number examined. Indican positive in twenty-five per cent. of these cases.

Involutional psychoses: Thirteen per cent. of the total number examined. Indican positive in fourteen per cent. of these cases.

Organic psychoses: Twelve per cent. of the total number examined. Indican positive in twenty per cent. of these cases.

Paresis: Eleven per cent. of the total number examined. Indican positive in ten per cent. of these cases.

Paranoia: Six per cent. of the total number examined. Indican positive in nine per cent. of these cases.

Psychoneuroses: Seven per cent. of the total number examined. Indican positive in twelve per cent. of these cases.

Excitation psychoses: Two per cent. of the total number examined. Indican positive in twelve per cent. of these cases.

Dementia praecox: Eight per cent. of the total number examined. Indican positive in eighteen per cent. of these cases.

Toxic psychoses: Seven per cent. of the total number examined. Indican positive in eleven per cent. of these cases.

Albumin and casts were found in six per cent. of the cases of the manic depressive group, which was a higher percentage than the findings in the other psychoses. Bile, leucocytes, and epithelial cells were found in a very small amount. More detailed examinations as to the elimination of urea, acetone, and diacetic acid were not made.

Gastric Analyses. I shall simply mention, in passing, the examinations of the gastric contents as only a few were made; the findings were not constant and the number was not sufficient to warrant any conclusion.

Examination of the Feces. Thirty-three cases of the manic depressive group were examined by Doctor Rosenberger and Doctor Terrell for the presence of occult blood and amoebe. Fifty-five per cent. of the manic depressive group showed occult blood, while sixty per cent. of these cases showed the presence of amoebe. The relation between the presence of amoebe and occult blood was not constant. Doctor Rosenberger and Doctor Terrell were of the opinion that the presence of amoebe did not play any part in the etiology of the disease. They also suggested that the presence of occult blood was due to a toxic substance which caused a relaxation of the vessel walls and a subsequent leakage of blood into the intestinal tract. The writer, however, would venture to suggest that this reaction is possibly due to a toxic substance or chemical changes in the gastrointestinal tract giving a positive blood reaction.

Blood Examinations. The blood picture of the manic depressive group showed no special characteristic other than the changes which were due to some secondary condition such as lymphocytosis in tuberculosis, secondary anemia, and marked anemic conditions dependent upon physical disease, and leucocytosis in the presence of pus infections. It has been my own observation that paresis is the only psychosis which presents a blood picture almost characteristic, namely, a diminution of the polynuclear cells with an increase of the small lymphocytes.

Blood Pressure. Dr. Leonard Raftery, at my request, has been studying the blood pressure of the manic depressive group during periods of excitement and periods of depression. His findings coincide with the findings of Craig, of London, namely, that in periods of excitement the blood pressure is lower than normal and in periods of depression it is higher than normal, the two conditions varying from ten to fifteen millimetres below and ten to fifteen millimetres above normal.

Pathological Findings. In studying the pathological findings of more than two hundred cases I have noted particularly the fibrous changes in the most important viscera, such as the heart, liver, and kidneys. My object in doing so was the possible view that the manic depressive group was dependent upon a low grade toxemia which in turn produced a mild low grade fibriloid change throughout the entire system. Of the first fifty-one cases studied, thirty-one per cent. were cases of the manic depressive group.

Atherosomatous changes were noted in: Twelve per cent. of the total number, twenty-five per cent. of the manic depressive group, twelve per cent. of the remaining psychoses.

Chronic interstitial myocarditis in: Twelve per cent. of the total number, thirty-one per cent. of the manic depressive group, three per cent. of the remaining psychoses.
Cirrhosis of the liver in: Twenty per cent. of the total number, twenty-five per cent. of the manic depressive group, eleven per cent. of the remaining psychoses.

Renal changes in: Thirty-five per cent. of the total number, thirty-eight per cent. of the manic depressive group, thirty-four per cent. of the remaining psychoses.

The higher percentage of fibroid changes in the manic depressive group in comparison with the other psychoses rather supported this view until a further study of forty-three cases was made.

Of these forty-three cases, sixty per cent. were cases of the manic depressive group.

Chronic myocardial changes were noted in: Eighteen per cent. of the total number, twenty-three per cent. of the manic depressive group, twelve per cent. of the remaining psychoses.

Cirrhosis of the liver noted in: Thirty-seven per cent. of the total number, thirty-eight per cent. of the manic depressive group, thirty-five per cent. of the remaining psychoses.

Renal changes noted in: Forty-nine per cent. of the total number, fifty per cent. of the manic depressive group, forty-eight per cent. of the remaining psychoses.

These findings showed that there was possibly a higher percentage of involvement of the manic depressive group than the other psychoses. Not convinced, however, I then studied a group of one hundred and forty-seven cases, forty-three per cent. of which were cases of the manic depressive group.

Atheromatous changes were noted in: Fifty per cent. of the manic depressive group, forty per cent. of the remaining psychoses.

Chronic myocardial changes noted in: Eleven per cent. of the total number, twenty-two per cent. of the manic depressive group, fifteen per cent. of the remaining psychoses.

Cirrhosis of the liver noted in: Twenty-two per cent. of the total number, thirty-three per cent. of the manic depressive group, twenty-five per cent. of the remaining psychoses.

Renal changes noted in: Eighty-five per cent. of the total number, ninety-two per cent. of the manic depressive group, eighty per cent. of the remaining psychoses.

Uterine changes noted in: Thirty-two per cent. of the total number, thirty-three per cent. of the manic depressive group, thirty-one per cent. of the remaining psychoses.

In the study of over two hundred cases, fibroid changes seemed to be more of a constant finding in the manic depressive group than in the remaining psychoses. This percentage was reduced, however, as the total number of the cases studied was increased. I do not consider these fibroid changes of any particular importance from the standpoint of etiology on account of the fact that patients of the manic depressive group live a longer period than those of the other psychoses and the fibroid changes in many of these cases were concomitant with or secondary to old age.

General Summary

So far as I have been able to demonstrate, there are only a few findings of clinical significance. Indicanuria is a more frequent finding in the manic depressive group than in any other psychosis. Whether this finding is due to a toxemia which acts upon an already predisposed nervous system and produces the manic depressive insanity or whether it is due to an autointoxication as a result of the manic depressive insanity is open for conjecture and further study. It is true that physiological chemists have been able to demonstrate the presence of indican in a relatively high percentage of supposedly normal individuals. These persons, however, may be suffering from autointoxication with no definite clinical manifestations, and I do not think that this fact should exclude the value of the finding of indican in the manic depressive group, for it is a well known fact that certain individuals possess a natural immunity to certain toxic substances, such as bacteria and the chemical products, and they are constantly eliminating them from the system without any noticeable pathological change.

The gastric examinations, blood examinations, and examinations of the feces have little clinical significance.

The positive reaction of occult blood in the feces opens a very interesting subject for future study. If it is blood, its etiology would be indeed interesting. If it is some unknown chemical substance, found especially in the feces of the insane, which gives this positive reaction for occult blood, it is certainly an unlimited field for the physiological chemist. If such unknown substance could be definitely demonstrated, most likely we would have a more definite understanding of the etiology of the various psychoses.

Blood pressure is certainly of value in the study of the manic depressive group.

Changes in the scalp, skull, cerebrospinal fluid, brain cells, and so on are not constant and are of little value in determining the exact pathology or the etiology of the manic depressive group.

The changes in the other viscera are not pathognomonic of any particular psychosis, as variations in the findings can be attributed to secondary changes due to old age, disease, and so on.

Those of us, however, who have stood by the bedside and studied clinically these patients, who showed the fetid breath, the dry, parched skin, etc., and have seen these conditions clearing up under the judicious use of purgatives and eliminative treatment, cannot help but be inclined to regard the etiology as a toxic condition acting upon an already predisposed nervous system. This fact, however, has not been demonstrated by clinical and pathological findings.

Thirty-fourth and Pine Streets.

Charity: Some Thoughts on Its Use and Abuse.

By H. E. Tompkins, M. D., D. D. S.

New York.

"We are bound to thank God always for you, brethren, as it is meet, because that your faith groweth exceedingly and the charity of every one of you all toward each other aboundeth." (2 Thess., I: 3.)
"But speak thou the things which become sound doctrine, that the aged men be sober, grave, temperate, sound in faith, in charity, in patience."

(Titus, ii: 1-2.)

"But the end of all things is at hand, be ye therefore sober and watch unto prayer and above all things have fervent charity among yourselves, for charity shall cover a multitude of sins." (1 Peter, iv: 7-8-9.)

"These are spots in your feast of charity, when they feast with you, feeding themselves without fear," (Jude, xii.)

"I know thy works, and thy charity, and service, and faith, and thy works; and the last to be more than the first." (Rev., ii: 19.)

In the work of dispensary charity, the apostolic words quoted above form a story in themselves. The story, of course, is not as complete as it should be for the reason that it is not up to date and that the several writers had more faith in humanity than we of this day. They did not realize the uses and abuses of the medical and dental dispensaries by the twentieth century mendacious pseudo-mendicant. It is evident from the excerpts that charity was extant in early times. It probably has been practised from the very beginning of the world. Its aim is and was to assist the worthy poor to conditions above those which they enjoy, be it in health or wealth. There is no doubt that promiscuous charity is responsible for the present system of mendicancy, allied or associated beggary, as found in Europe and Asia. It gave rise to the profession of beggary, to the formation of the hands of "yeggmen." By asking aid in times of real need men found the public to be gullible and the fruits of beggary to be greater than those of legitimate employment and so a "what the devil do I care here comes another succor" spirit was fostered and engendered. That all beggary is a fact is evidenced by the fraternal spirit demonstrated by tramps who by code signs classify each house at which they ask alms. Promiscuous and ill advised charity begets a display of panperism designed to instill pity that the appeals may be more effective. It inspires the beggar to contort his body to inconceivable shapes, to dissemble the appearance of the loss of a leg or arm which is very much present, to bandage a part as though an injury were present, to exhibit the thousand and one abnormalities which add to the play upon the sentiment of the unsuspecting giver.

Some years ago beggary become so prevalent, so persistent, so arrogant, and so much of a nuisance that the Poor Laws of England could not cope with the pernicious array. It was not until 1860 that any control was gained of the menace when drastic laws were passed and enforced. At this time, too, the first charity organization for systematic almsgiving was formed. Following this organized charity was established in the larger cities of the western world and professional beggary was thus held in check until about six or seven years ago. Since 1907, however, the increase of beggars not only has been noticeable but it is becoming alarming. This condition is more noticeable in the medical and dental dispensaries than in any other place. Unless it is checked, it will be found that the horde of charity seekers will be greater even than in the days of the Poor Law.

General charity and medical charity are not afflicted with the same elements to any great degree. The professional beggar seeks for money. When in illness, he employs the best medical talent he can get. Medical charity appeals to two classes: the worthy poor, who dislike to seek charity and who do not take an unseemly advantage of the kindness offered, and the unworthy rich, who revel in that to which they are not entitled. The unworthy rich dedicates it far below his standard of decency to beg money. He reasons that to do so tends to place him in almost the criminal class, in a stratum of society in which he does not care to move. Indeed, it would be a high crime against his pride to stoop so low as to ask for money.

As evidence of the growth of the evil, look for an instant at the statistics for the years 1907 and 1912. In 1907 there were 99 hospitals and 107 dispensaries in New York City at which there were 2,800,000 consultations. In 1913 there were 119 hospitals and 212 dispensaries at which there were over 4,000,000 consultations. When it is remembered that New York's population is something like 5,500,000, it would seem that a large proportion of the population availed itself of the institutions.

While it is true that a large number of the inhabitants of this city are living lies or "hall rooms" (as far as their financial condition is concerned), it must be admitted that a great many, less than four fifths, of the inhabitants are unable to pay a reasonable fee for medical attention. I do not believe that this, the richest and greatest city in the world, has more than one tenth of its population so poor that it cannot pay for this service. If you think all dispensary patients are poor and deserving, read on. A child, while playing on the stairs leading to the 145th Street elevated station, fell and broke his arm. His mother took him to the dispensary of the J. Hood Wright Hospital (now called Knickerbocker) for treatment. The mother tells the story thus: "I took him to the Hood Wright Hospital and had him fixed, and all it cost me was one dollar for a picture and seventy-five cents for something else." This woman, I am told, owns the property situated at 311 West 145th Street, which is probably worth about $40,000.

This same child, it was found by the school inspection, has adenos which require removal. The mother, well able to pay, says she will take the child to the same place.

A woman living on MacCombs Place had some trouble with her ear. She visited and was visited by a physician somewhere on Washington Heights. She boasts of the fact that she had to pay him from one to five dollars a visit and obtained no relief. She went to the Harlem Eye and Ear Infirmary where the condition was treated and cured, and all it cost was about a dollar. This woman is in good financial condition and could pay, and pay well.

I know of patient after patient who came to me at the Calvary Church Dispensary who were well able to pay for services. I am free to say that I saw
to it that they did pay or they did not get treatment. For instance, the child of a waiter, at one of the downtown restaurants, earning from forty to fifty dollars a week, came for treatment which ninety per cent. of the medical men in New York would be happy to give for no more than ten dollars.

The wife of an insurance man earning about $2,500 to $3,000 a year applied for dental treatment which could be had almost anywhere for fifteen dollars.

A woman, owning a confectionery store (a nice one, too) on Eighth Avenue applied for treatment for rheumatism. She, in confidence, told a friend that business was very bad for she could not put more than $175 in the savings bank that month (note that savings bank). This woman later went to Mount Clemens for treatment.

A few cases of this sort leads one to agree with the apostle when he says, "for charity shall cover a multitude of sins."

This great army of unworthy rich has been created by the dispensaries themselves or by the physician who likes to be considered popular and who works for a large and unwieldy class. The managing force in each dispensary strives to make the record of his institution larger than that of the others by practically inviting anyone and everyone to come to that infirmary. Indeed, some men of whom I know beg the class members to bring a friend the next time. Smatters just a little of the Baxter Street methods of a few years ago, doesn't it?

Why are there so many dispensaries? There are two reasons: first, some misguided mortal feels that charity in the shape of medical services is needed; second, one or more physicians feel that they must have some place where they can practice on patients or where they can add to their practice by weaning some of the patients from the dispensary idea or where they can give their services freely to the unfortunate worthy.

Is it necessary that there be so many or more dispensaries so the men may get more training? I do not think so. Pick up your journal and look over the "want ads." You will find one or more requests for men to attend upon some hospital or sanatorium for which fair pay is offered. You don't want that: then go to almost any of the dispensaries already established; it is easy to secure an appointment. This desire for more training is commendable, it shows a true spirit of progressiveness, but let us be like the "aged men . . . sober, grave, temperate . . . ."

The patients who can be added to one's practice are few and even after they have been added they do not make good patients, for they are unreliable and not productive of good nor even reasonable fees. They are thankless, lacking in appreciation, gratitude, and loyalty, for at the slightest provocation they drop from sight, being neither "sound in faith, in charity, in patience."

The desire to do for suffering humanity is laudable. It is almost divine, for does not the Good Book say, "It is more blessed to give than to receive"? The feeling of satisfaction is great and wonderfully pleasing that results from the giving. But, unless the giving is done in a systematic manner, unless the recipient is investigated and found worthy, unless the giving is surrounded by enough "red tape" to make it almost impossible for the undeserving to benefit, the giving will soon become a curse.

What does the foundation of new dispensaries mean? It means that an appeal is to be made for more patients, made in any way that will be productive of numbers, for no dispensary can exist (city institutions excepted) unless it is supported by a large number of patients. Dental dispensaries of which six new ones are being established, are particularly pernicious, for they are attended mostly by children. Many of the children are those of people well able to pay for services. The children are told in the school inspection that the teeth need attention. They tell their parents who advise the kids to go to the place recommended by the inspector which is invariably the dispensary. The moral influence of sending the children to these places is bad, very bad. For they find that their teeth will be treated practically free and since every one is willing to be given and to accept that which is given, they go, from force of circumstances and parents, to the institutions, to breed a new army of suppliants, becoming "spots in your feasts of charity, when they feast with you, feeding themselves without fear."

How can the curse be mitigated? Investigation of applicants seems to be the only real solution. But the task of investigating is far too great for the numbers of workers connected with the institutions. It has been suggested that the city be divided into districts, each to be served by a dispensary within its limits, all applicants from outside the district served are to be referred to the institution provided for them in their own districts.

This arrangement will not satisfy nor tend to correct the evil, for members of the district, in fair circumstances, will still take advantage of the kindness of the institution. The arrangement can be made more effective if a census of each district is taken, noting the home conditions, the occupations and weekly or monthly salary of the working members of the families and the number and names of members of the family; then an index system which is accurate and reliable will be had to which reference can be made upon the application of a patient. With this information at hand, the clerk can give or refuse a patient a card of admission with a degree of certainty and assurance that he is right. By this addition the falsifying applicants can be exposed and turned away from the institution; or he can be charged a good fee which can be divided between the physician and the institution. This addition will stop the migration of the more daring applicants by forcing them to remain in their own districts.

Perhaps a new family moves into the district. Why not give palliative treatment until an investigation can be made? Now this can do no harm for the average dispensary patient is not dangerously ill for if he were he would not, or could not, go to the institution for treatment. You must admit that few patients die or become even danger-
ously ill from the conditions that bring them to the infirmary.

The indexed district plan is the right way of aborting the evil. A second plan is that the physicians can refuse to serve at the dispensaries. This would mean that the institutions must close for with none to treat the patients, patients will not come. This method has one serious objection, the really poor and needy person will suffer and be neglected. That is not fair. As I say, the only serviceable method is to index the districts, treat the worthy poor free and charge the richer fakers the regular office fee in addition to a regular prescription charge. Then and only then can the admonition of Titus be followed, “But speak thou the things which become sound doctrine, that the aged men be sober, grave, temperate, sound in faith, in charity, in patience.”

What is the effect of this ill advised charity? I grant you that business and ethics do not mix well, but there are times when business must be considered. This subject furnishes one of the times when we must look at the business side of the profession.

The establishment of, and the request for attendance at, dispensaries for and by the public tends to suggest, that few but the rich and foolish should think of going to a private practitioner for treatment. It suggests the thought—Why should I pay for such service when I can get it for nothing? Such thoughts when put into practice mean that your fees will be lowered and lessened. It means that the already low yearly average income of the physician will be brought so low that many will not be able to live. That many will be brought to the point where they must seek charity to provide a home and a livelihood for themselves and their families. They must become victims of the very evil which they in the goodness of their hearts sought to build up and thereby benefit humanity. Should such things occur? Understand me! I do not think that dispensaries should be abolished nor do I think treatment should be refused in emergency cases nor in cases of the deserving poor. I do think, though, that treatment should be refused where there is any evidence whatever that the person can afford to pay or, if it is not refused, that a fee equal to the office fee of the attending physician should be charged. Then it can be truly said: “I know thy works, and thy charity, and service, and faith, and thy patience, and thy works; and the last to be more than the first.”

2105 Seventh Avenue.

BLOOD LETTING APPARATUS.

By Elliott C. Burrows, M. D., New York.

In 15,000 personally observed cases where blood was obtained for Wassermann or gonorrheal complement fixation tests, or other serological examinations, the need of a blood letting apparatus has been amply demonstrated. This apparatus is especially applicable in the case of very young infants, or in older subjects where a vein is not visible, its greatest utility, however, being in infants. The apparatus is simple, compact, inexpensive and can be thoroughly sterilized in a few minutes.

The infant is held face down across the lap of the nurse and the skin rendered surgically aseptic in the scapular region; with a broad Hagedorn needle make six to ten punctures, place the glass cup over the punctured area and manipulate the suction pump.

40 East Sixty-second Street.

CLINICAL OBSERVATIONS ON CANCER; ITS TREATMENT AND CURE BY CHEMICALS ALONE.

By Kenneth J. Junor, M. D., Brooklyn, N. Y.

We speak of the exact sciences, but Nature’s processes alone are exact. Experience teaches that to advance in our knowledge of any science, either theoretically or practically, the more closely we follow Nature the greater our advancement.

The physician’s first and best work is to find out what is obstructing Nature in disease. Its removal marks his ability and skill. We are learning rapidly that the entire range of Nature’s processes have a chemical basis. The power behind the mechanical in the body and among the planets, is chemical. The final distinction between male and female, will be found to be chemical. Who knows,
at present, how much of speech is attributable solely to chemical changes?

The human body is a perfectly equipped laboratory for the production of chemical combinations, either for nutritive, protective, or curative purposes. When this equipment becomes disordered, or its perfect action is interfered with, what we call disease results. To keep this equipment in order, remove impediments to its perfect operation, supply deficiencies, and repair injuries to its mechanism, is the Herculean task of the physician. Simplicity to conceive of it, is staggering. It is plain, however, that in the curing of disease, the greatest problems are chemical ones. In such a presence, what a commentary on the curative methods as taught in our medical schools during the last fifty years, in which no attention worth counting has been given to therapeutics or physiological chemistry. No wonder the profession rushed to the mechanical refuges of surgery, and the general practice of medicine has become almost a byword and a shame.

The chemical combinations in the body are constantly undergoing molecular changes. This is why medicine cannot be an exact science, until the complexity of these changes is thoroughly understood. For that very reason, its demand for keener powers of well balanced judgment, on the part of the physician, is greater than that of any other profession. Since it deals with human life, its responsibilities are proportionately greater. Indeed it was the deep sense of this great responsibility, by the profession, that led to the practice of vivisection, without which exact knowledge in physiological chemistry would be impossible, and the practice of medicine little else than empirical, but slightly removed from the Indian medicine man.

Under the great advances in physiology and especially chemistry, medicine is advancing toward the knowledge of not only what must be done, but why it should be done. So that the medicine of the future will in its nature be more chemical than surgical, more constructive than destructive, as too much of it now is. The physician of the future will be trained in biology, therapeutics, physiology, and chemistry. Of these, medicine has known next to nothing in the past. How much more will the physician be able to help humanity, by an exact knowledge of body metabolism. The methods of Nature will be his vade mecum. He will study them more profoundly and imitate them more closely, as revealed in the laboratory of the body. Everybody realizes the marvelous advance in the treatment, along these lines, of diphtheria for example.

The ignorant cry against chemicals of late years has been due, partly to lack of skill in preparation, partly to ignorance of how to use them, and largely to adulteration. In using them the physician obtained either no result or a bad one, to his own and his patient's disgust and, worst of all, to the loss of his own and his patient's confidence. There is not a shadow of doubt that the trend of scientific investigation, to-day, for the cure of disease, is physiological and chemical, and on the lines of Nature's methods.

In fact an entirely "new medicine" is well under way whose dominant tendencies are (1), the close study and imitation of Nature's methods; (2), it will be constructive, not destructive, prophylactic and preventive. Scientists are only now beginning to appreciate the wonders of the human body, and to see that it is the most marvelous thing in the physical universe. The greatest of its marvels is that all its powers, mechanical, emotional, and even intellectual, are moulded and maintained in operation, if not directly brought into being, by chemical agents.

Properly to appreciate their wonders, and their possibilities, in the cure of disease, it is only necessary to compare the long and tedious processes through which human science produces diphtheria antitoxine, for instance, with the instantaneous production, in the body, by the Divine chemist, of a more perfect product, the instant the bacillus emits its poisonous toxine. Even if it be a new toxine, historically, this marvelous mechanism will instantly manufacture a new antitoxine to meet and destroy it. Its limitations in protecting us completely from attacks of disease are, in all probability, caused by our ignorance of the laws of healthful living. Thus by ignorance or sin, the vital powers are lowered, our resisting ability is destroyed, the toxic elements increase and overwhelm the antitoxine, the patient succumbs. It is one of the marvels of science that we are able to cause the production of these antitoxine elements in another animal, extract them from its blood, inject them into the dying human subject, and save his life. This is high science, but after all it is only discovering what Nature can do, not doing it. The mechanism, the manipulation, the elements, these are all there. This is the real marvel, revealing itself to the present age—the mysteries of body metabolism. It is the vision of this science, higher than any thing human, that distinguishes such a scientist as Sir Oliver Lodge who, while others watch the flash of the gun, fixes his attention on the man behind it. This is the true scientific spirit. Through such men and such achievements, this age is inspired to a new and confident hope and assurance that a new knowledge of life and its meaning, are imminent. A new hygiene, a new prophylaxis, a new protective medicine has materialized. Human metabolism is becoming an open book. Disease is being conquered, and by Nature's own lytic methods. Dr. Carrell has shown us that science, again by imitation, can actually promote the growth of new tissue extra vitam. Few would have believed this a year ago. Last year the writer had the temerity to prophesy the near accomplishment of this great feat, in a paper to be read before a medical society. When I read this paragraph to some friendly critics, I was advised to strike it out as it might awaken unfriendly criticism, and I omitted it. I believe the new medicine will save and restore much that in our ignorance we have handed over to surgery to destroy. The writer believes that the major part of present surgery will become a memory, a horrid nightmare, and be forgiven on the justifiable plea of former ignorance.

Physiological chemists have discovered that the peristaltic action of the intestines is established and maintained by a subtle chemical agent, which they designate a "hormon." It is manufactured in the ductless glands and then issued to this local organ.
to operate it, as steam operates an engine. Not only this, but the chemist has isolated this element, and put it on the market, so that the modern physician can administer it to his patient and restore that action, so necessary to life, if from any cause, as atony, or operation, it has become impaired, or is destroyed. And so of other "hormons." Such discoveries as these throw into absolute shadow the most brilliant achievements of modern surgery, because it is treading in the very footsteps of Nature, and is science of the very highest type.

THE WRITER'S CONJECTURE AS TO THE CAUSE OF CANCER.

Etiology. A year ago, observing the local and systemic peculiarities of cancer, the systemic birth and local destinations of these subtle hormones, and the remarkable effect of the chemicals I was using on cancers—chemicals chosen specifically because of their well known systemic and local action—I conjectured that, possibly the cause of cancer might lie in some derangement of, or interference with some one or more of these hormones. It was only a passing thought. Until last August, it was cabled from London that Doctor Bashford, the secretary of the Million Dollar Cancer Research Fund, had stated, before the International Medical Congress, as his opinion, after ten years of research, that these hormones might be found to be a cause of cancer. This of course gratified me very much, for his conclusion was reached in the laboratory, on animals: mine, in the office, at the bedside, and with human subjects.

Treatment. It is now over ten years ago that, moved by the above considerations, and an inherent desire to attempt the solution of unsolved problems, I ventured to enter upon the task of the treatment of cancer by chemical agents. I selected the following agents: An animal extract, potassium, calcium, sparteine, and a tissue stain. I have treated some sixty cases, a part hypodermically, and the rest by internal medication; four of them were presumably tuberculous, and the rest presumably cancerous. Eighteen were, by microscopical examination, proved to be cancer; in the remainder the diagnosis was made from the external gross appearance and history. In the majority, however, the diagnoses were made by eminent men. Coming to me to avoid the knife, it was naturally difficult to secure microscopic confirmation. Some had been operated upon as many as six times by eminent surgeons. Eight were malignant epitheliomas or sarcomas. Three only were in good physical condition. None but were exhausted financially from many treatments, all of which had failed. Some were absolutely hopeless cases, before reaching me; but in no case, save one, did the treatment fail to have a favorable effect. This last was a case of epithelioma of the external genitals, in a lady eighty-five years of age. The treatment had to be abandoned by me, because I was financially unable to carry more than a few patients without remuneration. Ten were internal, in the sense that they were not skin cases. In ten cases the hygienic and other conditions were most unfavorable. One patient, aged seventy-five years, had an x ray

...
much food for thought. At the same time there are some very significant opinions and facts which completely undermine the basis of any assumed scientific justification for "more surgery."

Dr. Robert Abbe, of this city, is quoted as saying at the late International Congress in London: "Surgery has expended its utmost force in cutting out every vestige of disease, or in destroying by caustic, cautery, or freezing. These occasionally cure the patient but they never cure the disease; they only remove it. We must look to forces like organic chemistry, biochemistry, Röntgen rays, or radium."

Why is it that the great research genius, Paul Ehrlich, and his companion Wassermann, have, since the discovery of the great chemical remedy salvarsan, turned their skill and magnificent resources to a search for a chemical cure for cancer? They have evidently abandoned all hopes in surgery, vaccines, et al. There could be nothing more significant as to the trend of world science.

Dr. John B. Murphy, of Chicago, one of our greatest surgeons, stated last year at Rochester "that we had made little, if any, progress in our treatment of cancer, during the last twenty-five years," and we all know that this treatment has been almost exclusively surgical.

Now on returning from the International Congress in London he declares "that perhaps the most hopeful discovery of the last fifty years regarding cancer, is the possible immunization of a certain variety of Japanese mice." This statement speaks volumes for the honesty and great courage of this great surgeon, but points out the slight probability of any future triumph in store for surgery, with regard to cancer. No! Surgery is war! often necessary, often purifying, often just, but, nevertheless, war!

Is it not clearly recognized that blows, pressure, irritations (among which surgery must be classed), often act as a secondary, if not the primary cause of cancerous growth? So also that seemingly benign tumors, after operation, recur as malignant. And in operation it is utterly impossible to tell whether or not all the infected cell tissue has been removed. Then there are really few surgeons with sufficient skill, or with suitable environment, for the extirpation of cancer. Further, and this is of the utmost importance to the whole world, especially to its sufferers, the surgical treatment of cancer can never be anything but institutional. It can therefore hold out only the most meager hope of relief to the multitudes whom no institutional treatment can ever reach, save at great cost and inconvenience; whereas, if some simple, easily available remedies such as these can be administered by the family physician, how many thousands of lives may be saved. While the work of the laboratory and the institution has its place, and an admittedly large one, yet the work of the family physician, in the office and at the bedside, must necessarily cover nine tenths of human needs in disease.

Moreover, we believe that institutional treatment is not the most desirable. It tends to eliminate the humane elements from medicine, a vital necessity to its best work. The writer thinks it a most dangerous tendency for medicine, that millions of money are poured out for institutions, without being accompanied with even more millions for improving the efficiency and opportunity of the ordinary family physician. To lower the standard and standing of the family doctor, or to diminish his own sense of honor or the respect of the community for him, is a fatal mistake. That mistake has been gradually growing, largely through institutional methods, hence discontent within the ranks, and much contempt outside are more and more imminent. Concentration in the practice of medicine is suicidal to the best interests of the community.

The great advances of modern science are emphasizing the importance of the relations between the individual, the community, and the government. Medicine, because of its intimate and intricate relations with all three must take first rank in the settlement of these relations. As between institutional and private practice, the former stands to win, in the earlier rounds, for institutional interests are strong, the public ignorance as to the importance of the problems is very great, the institution is nearer to the ear of the State, and governments are proverbially deaf to persons and things more remote. The work of the family physician is of infinitely more importance to both the public and the government, than that of any or all of our medical institutions combined. This, without depreciating for an instant or a fraction the vital importance of the laboratory, the hospital and the clinic. The well equipped family physician is the State's greatest asset. At the strategic points of the community's battle with disease he stands. In epidemics he is a city of refuge, and in prevention a needed counsellor. Institutional and costly practice, as a rule, reach two classes, the rich and the poor, often pauperizing the latter to a dangerous degree, breeding distrust in the average practitioner, and filling his own heart with jealousy. The care of the family as a group, by the general practitioner, is of infinitely more importance to the State and the community than the care of the individual, in the institution by the specialist. Only a minimum at best, could our institutions accommodate in widely spread infections: and only a few, under the tendencies of specialism, can retain that breadth and wide sympathy, which so often does, and always should, characterize the family physician. If the State and the public shall permit the specialist and the institution to usurp the place, or lower the standing of the physician in the family, the dangerous and suicidal attempt will be made to care for the head by cutting off the limbs.

CONCLUSIONS.

Regarding the physiological action of this treatment, as far as laboratory tests have been available it acts powerfully on the white cells of the blood, more especially the large mononuclear leucocytes, increasing their number several hundred per cent, in a few days. This seems in line with Nature's own method of attack upon disease. The cancerous tissue is gradually destroyed, without injury to the patient. In my earlier treatments, patients lost flesh rapidly, and I had some difficulties with high pulse. These difficulties I have, however, eliminated, and the patient's general physical condition.
is not interfered with. Of course in many cases intercurrent diseases have to be watched as well. One patient with pulmonary tuberculosis (diagnosis made by an officer of the Board of Health) lived constantly under such unsanitary conditions as to be really appalling, had a cancer on the nose and cheek, penetrating the eye. This was cured, and for several months I received negative reports from the Board of Health as to the presence of bacilli. The patient, for the last two years, apparently free from both diseases, is hard at work from day to day, when he can get it, though sixty-eight years of age.

Surely this treatment must powerfully stimulate the white cells in the blood to the production of antibodies and must possess specific qualities of high potentiality; if it will inhibit the growth of a microscopically determined malignant sarcomatous tumor, attaining the dimensions of half a goose egg in a few weeks, and accomplish its disappearance. All of this it has done.

Notwithstanding our marvelous advances in science, we have as yet only scraped the surface of the possibilities of the human body. Its secrets are the deepest secrets; and when we have pierced the physical ones we will see greater things within and beyond.

Abstracts and Reviews.

THE AIR AS A VEHICLE OF INFECTION.*

By CHARLES V. CHAPIN, M.D.
Superintendent, Health Department, Providence.

Until very recent years the air has been generally considered the chief vehicle of infection. Such diseases as malaria, typhoid, typhus, cholera, etc., were believed to be spread by aerial convection. Sewer air was considered an almost certain carrier of typhoid, cholera, and dysentery, and it was even believed that the old water courses of New York could be traced by the prevalence of disease. Open streets, ditches, and the like were confidently believed to give rise to epidemics of typhoid fever and malaria. The carbolized sheet and the saucer of chlorides were thought to be powerful means of preventing the spread of infectious disease, and, even at the present time, are fairly widely used for this purpose.

The earlier work on the bacteria seemed to lend considerable support to the belief in the air transmission of disease, since it was easy to think of the minute organisms being carried in the air. The resistance which certain bacteria showed toward drying was demonstrated by Pasteur, and added further support to the possibility of their being carried in the air. After Koch proved the nature of tuberculosis, a number of observers, among whom the names of Cornet and Pfluegge are prominent, showed that guinea pigs could be infected by the spray of coughing persons who were affected with pulmonary tuberculosis. All of these observations, and many others beside, seemed to establish the fact that the air was the great vehicle of transmission of disease from man to man.

It was the laboratory which first gave scientific support to the theory of air convection, and it was the laboratory again which first gave grounds for the disproof of this theory. The work of Winslow with sewer air, in which he demonstrated that bacteria were very rarely present even in this confined air, gave almost the first conclusive evidence against the air as a vehicle of infection. He found no pathogenic bacteria in sewer air except the colon bacillus, and in two hundred one litre samples this organism was present in only four. He showed that its presence in these four samples could be accounted for on the basis of droplet infection, the samples having been taken from regions in the sewers in which there was splashing of the water. This work also brought out the fact that even in the infected samples of air the number of organisms was extremely small. By actual comparison of results it was shown that the bacteria in the total amount of air needed by a person in a day were less than where found in ten c. c. of New York city water. As it is usual for a person to drink about a litre of this water each day, and, as no ill results follow this consumption of bacteria, it was unreasonable to suppose that the extremely small numbers of organisms present in the air could have any detrimental influence on a normal person.

This work first brought out the fact that the element of dose was of prime importance in the consideration of the transmission of disease by the air. The acidforming mouth streptococci are not found in air unless human being are present. Studies of the air in school rooms revealed this organism in the proportion of six coci to each one hundred cubic feet of air. The dose of these organisms received from this source in a school day was therefore insignificant.

It must be borne in mind that, in considering the air as an agent in the spread of disease, the presence of bacteria in dust is no criterion of the presence of these organisms in the circulating air: for their concentration in dust may be considerable while the amount of dust in the air is relatively so small that the concentration of the bacteria is reduced to an extremely small figure.

As already mentioned, typhoid fever was long thought to be spread by the medium of the air. Painstaking epidemiological studies; the discovery of the organism in water and foods; the occurrence of carriers; and the absence of its transmission from one person to another in hospitals, except by contact infection, have removed this from among the diseases believed to be air borne. The same may be said of cholera, dysentery, and summer diarrhea, all of which are now known to be transmitted by other means than the air.

In the early days of aseptic surgery the sterilization of the air was considered the most important preventive measure, and a surgeon would not hesitate to pick up an instrument which had fallen to the floor and continue to use it. Studies of the bacterial content of the air in operating rooms have shown the presence of pus germs, but we all know now that an infection of the operation wound is

---

*Summary of a lecture delivered before the Harvey Society, at the Academy of Medicine, November 1, 1913.*
almost invariably traceable to some direct contact, and never to the deposition of the air organisms. Here, again, it is a question of dose of the infecting bacteria.

Much evidence was brought forward to prove that typhus fever was air borne; and this belief was well established. It, however, was destined to fall before the hand of science, and it has been shown that the body louse is probably the sole means by which this disease is transmitted. This discovery throws much light upon the epidemiology of the disease, for the incidence of the disease, its regional prevalence, and its seasonal occurrence agree precisely with the habits of the body louse.

Smallpox students argued for the air transmission of this disease, and showed its prevalence to be greatest in the region of smallpox hospitals, infected ships, and the like, diminishing proportionately with the distance from these centres. Other facts were adduced to prove the air convection of the disease. Further studies have shown, however, that the prevalence of smallpox is explicable on the basis of contact infection, and the disease has been shown not to spread through the air in hospitals, but solely by contact. Bubonic plague has fallen out of the group of air borne diseases since the discovery of the rat flea as an agent of transfer. Even pneumatic plague, which has been shown to be transmissible from man to animals through the droplets from coughing, is probably not air borne, for the dose of bacteria in the air immediately in front of the mouth of a coughing person is in no way comparable to the minute dose that might be present a few feet away. Strong and Teague have shown that the air expired during quiet breathing does not contain the plague bacilli. It is almost certain that when we know more of the disease we will find that contact infection will account for the great ease of transmission of pneumatic plague.

Mediterranean fever is now known to be spread by goats’ milk, and influenza, which has long been believed to be carried long distances in the air, is now known to be spread solely by contact, or by means of droplet infection. Pneumonia has not yet yielded up the secret of its mode of transmission, but the fact that it can be cared for in the general hospital wards without its spread to the other patients, and the constant presence of the pneumococcus in the mouths of a large proportion of healthy individuals both point away from the air as the vehicle of its transmission.

Turning now to the more distinctly “contagous” diseases—scarlet fever, diphtheria, measles, whooping cough, etc.—we again find the accumulation of evidence leading us toward the view that they are not air borne. In scarlet fever the idea that the desquamated cuticle carried the infectious agent fell in with the air transmission of the disease. The fact that the Klebs-Loeffler bacillus is very resistant to drying was believed to confirm the view of the air spread of diphtheria. But it is now known that the desquamated skin from scarlet fever patients does not carry the virus, and diphtheria has been proved to be spread by contact almost exclusively. In many hospitals these diseases are all cared for in the same ward, each class being housed in a separate cubicle. The walls of the cubicles do not extend to the ceiling, so that there is free air communication between the patients ill with the several diseases. Yet the diseases are not spread from one patient to another under these conditions. We may go further, for in a number of hospitals these diseases are not even separated by the partitions of cubicles, but are nursed in adjacent beds in a common ward. The only precaution is the observance of strict asepsis on the part of the attendants.

A case of one type is “bariered” from a case of another type of infectious disease merely by the presence of a characteristic card on the bed to indicate to the nurse that she is to observe strict aseptic precautions in passing from the care of one to the other. Under these conditions, where there is no isolation except through the prevention of contact transmission, we find that the diseases do not spread from one patient to another, thus conclusively ruling out the air as a means of their transmission.

The same statements may be made concerning the transmission of rubella and chicken pox as have been made in connection with scarlet fever, measles, diphtheria, and whooping cough. The spread of all is certainly almost exclusively through contact.

Pulmonary tuberculosis belongs in a class by itself in this consideration. It is too chronic for accurate observation in man. The fact that it is located in the lungs; that the bacillus is resistant to drying; that the bacilli are expelled in very large numbers in the sputum; that droplet transmission to animals is easy; that the bacilli are abundant in the dust of rooms inhabited by tuberculous persons; all go to make a fairly strong case for the possible air transmission of this disease. But we must recall that the conditions of the infection of animals by holding them directly before the face of a coughing consumptive, or through the medium of the dust collected from an infected room, are probably seldom existent so far as man is concerned. It is yet to be demonstrated that the bacilli are present in the air in sufficient numbers to provide an infecting dose through inhalation.

Anthrax is certainly often contracted without contact, but it is almost certain that the dust to which the wool sorters are exposed is sufficiently abundant to account for the transmission of the disease. Of poliomyelitis we know little, but there is not much reason to believe that air infection plays any material part in its spread.

The question of the air transmission of disease may be stated briefly in the following sentences:

Most of the important infectious diseases are not air borne. For tuberculosis alone is there valid evidence in favor of possible air transmission. Dust is not a factor of very great importance. The sewer gas bogey is dead.

Sedative Drops for Use in Gastric Disturbances.—Sée, in Paries Medical for April 5, 1913, is credited with the following combination for administration in dyspepsias associated with pain, and in cancer of the stomach:

R Tincture hyoscyami, 1
Tincture coni, 1
Tincture gentiane, 2
Olei anisi, 2

M. Sig.: Ten to thirty drops with each meal.
Prize Essays.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXXXIX.—How do you treat chancremosthoids? (Answers due closed October 15th.)

CXLI.—How do you treat the symptoms of senility, without organic disease, but showing approaching dissolution? (Answers due not later than November 15th.)

CXLII.—How do you treat prostatitis? (Answers due not later than December 15th.)

CXLIII.—How do you treat chronic constipation? (Answers due not later than January 15, 1914.)

CXLIV.—How do you treat gallstone colic? (Answers due not later than February 10, 1914.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only. All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The prize of $25 for the best essay submitted in answer to Question CXXXVIII was awarded to Dr. Arthur S. Risser, of Blackwell, Oklahoma, whose article appeared on page 871.

PRIZE QUESTION NO. CXXXVIII.

THE TREATMENT OF INSOMNIA.

(Concluded from page 923.)

Dr. Harold S. Glosier, of Wheeling, W. Va., says:

Whenever a deviation from health occurs we have, practically in every case, some disturbance of sleep and perhaps the most common of these is insomnia, which in my mind is but a symptomatic condition attended by the patient's inability to sleep the usual required length of time. The treatment of this symptom, insomnia, naturally implies the management of the basic condition of which it is a manifestation.

All the hereditary, digestive, toxic, circulatory, nervous, and reflex causes must be thoroughly and systematically investigated before the treatment is begun. Very frequently modes of living must be corrected, and the general physical condition of the patient brought up to par before any hope for recovery is to be had. Attention should be given to hygiene, both personal and general, and proper diet and exercises prescribed. Therapeutic measures are to be employed, not as a routine measure, but as they best fit the individual case.

In the hereditary cases I believe measures such as the warm bath taken at bedtime, but not followed by stimulating friction is conducive to sleep. Absence of sound and the elimination of light are important aids.

In the cases where the cause can be traced to digestive disturbances we should try to ascertain the exact character of the derangement and seek to correct the same. The stomach should not be empty, neither should it be overloaded, but sufficiently full to help decongest the head.

As regards cases where insomnia is of toxic origin we must rid the system of the poison as best we can. In this category, constipation acting as a cause of autotoxemia is the most important. Personally I do not believe in drugging the system for constipation, but rather to stimulate the intestinal walls to peristalsis by a simple soap suds enema given hot.

In the circulatory cases attended with insomnia it is obvious that we must treat the underlying condition whether it be organic, or functional, or both, before we can hope to benefit the patient.

Nervous and reflex causes of insomnia should be treated as each case calls for. Seek out the cause and do not treat symptoms only. I do not mean to say that we should treat the cause alone and not regard the insomnia, for in some cases we must relieve the patient temporarily.

To me any drug that can sufficiently master the organism to produce sleep belongs preeminently to the domain of dangerous drugs, and should be used with great caution and as a last resort. Chloral perhaps is our best weapon for combating insomnia, but in some cases sodium bromide acts sufficiently well. To me morphone, hyoscyne and other habit forming drugs should be our last resort. I have used a simple combination of trional, five grains, and sulphonal, three grains, successfully in treating insomnia regardless of the cause. I give this in powder two hours before bedtime, and again fifteen minutes before retiring, usually in a glass of hot milk.

In the treatment of this symptom let us remember that we are ever to be scientific, we must diligently search out the cause and correct it if possible, and only in cases of absolute necessity and then only with great caution should we resort to narcotics.

Dr. Morris Markowitz, of Philadelphia, Pa., says:

The treatment of insomnia requires a systematic investigation of any deviation from health, and this may be found to be due to any of the following causes:

1. Organic or functional diseases of the nervous system—in which hysteria and neurasthenia are predominant.

2. Deranged condition of other organs, causing a toxic state of the blood—from infectious diseases, gout, lithemia, and such intoxicants as alcohol, tea, coffee, or tobacco.

3. Diseases of the heart and bloodvessels.

4. The so-called simple insomnia—apparently unrelated to any other disease—will be found usually to be due to abnormal habits of life, such as regards diet, working hours, exercise and rest.

The treatment therefore is that of the cause whenever it can be ascertained.

The following are advantages to the treatment of insomnia will usually be found to be satisfactory:

Correcting the habits and mode of life of the patient, prescribing proper diet, and exercise, rest and hygiene. Where insomnia is traceable to indigestion, no food should be taken during the last few
hours before sleeping time, or if this is not advantageous the food should be of the lightest description. The use of alcohol, tea, coffee, or tobacco should be limited as far as possible, and especially abstained from late in the day or evening. A short period of rest by lying down—relaxation without sleep—after the midday meal, and a relatively early hour for retiring is recommended.

Often, the following measures used before retiring to sleep will answer well: A hot drink, such as a glass of milk, bouillon, or lemonade; a warm bath, not followed by stimulating friction, or simply a hot foot bath may induce refreshing sleep. When the feet are persistently cold and not relieved by hot applications, placing the feet in cold water, followed by friction until they are red, will have a good effect.

In many cases a change of scene such as a sea voyage or a season of camping will prove efficient.

**Medicinal treatment.** In most cases the use of drugs will have to be resorted to. Their use, however, should be only temporary. The dose at the beginning should be sufficient to produce several nights of sleep in succession, and after apparent rest of body and mind the drug should be reduced in quantity, and finally withdrawn. If necessary to use for any length of time, the kind of drug should be frequently changed. The following hypnotics are most commonly used: Veronal (five to eight grains), or trional (twenty to thirty grains), best given one or two hours before retiring. Chloral hydrate (five to ten grains) may be used in suitable cases.

The bromides may be combined with any of these drugs, and where gout or rheumatism exists they may be used in combination with the salicylates. Opium and its derivatives (codeine and morphine) should only be used when insomnia is associated with pain. In the same manner hyoscymus may be used. In the use of drugs the age of the patient is not to be lost sight of.

Finally, to avoid habit formation, it will be necessary to prevent the patient from knowing the particular drug used. In many cases the use of a "placebo" may give the patient a good night's sleep.

**Dr. S. J. Wright, of Akron, Ohio, says:**

Remove the cause. Muscular fatigue, as in a woodchopper, causes sleep. Nerve exhaustion, as in a professional man of sedentary habits, is productive of wakefulness. Detritus from the nervous system irritates the brain. It must be eliminated. Simple insomnia in an otherwise healthy person is best treated by elimination, and especially by increased oxidation. For this purpose the inhalation of ozone, filtered through oil of pine needles and eucalyptol, for half an hour, in the latter part of the day, is curative. An aid is the application of a glass vacuum electrode to the closed eyes for five minutes daily. The static efflorescence directed to the body below the head for twenty minutes, is useful. Use the positive pole, place the patient on an insulated platform. In lieu of this muscular fatigue may be incurred in a game out of doors, or one may ride in the open air for an hour daily.

In an emergency one finds great relief by lying on the floor with a blanket and pillow for a few minutes, then going again to the bed. It is well to habitually lie on all sides—front, back, right, left, for the relief following change of position.

Avoid tea and coffee during the afternoon. Retire early, rise in eight hours. Keep a clear conscience, recall pleasant hours.

---

**Therapeutic Notes.**

**Treatment of Digestive Disturbances in Young Children.**—R. St.-Philippe is credited, in *Gazette médicale belge* for May 15, 1913, with a discussion of the treatment of a group of disturbances occurring not infrequently in children eighteen months to three and even four or more years old, and including constipation, anorexia, faulty gas and secretion, etc., with resultant intoxication, anemia, poor nutrition, and defective development. Ultimately anorexia and irregular evacuation of mucous membraneous material are typically seen, and these conditions are often kept up by inappropriate treatment. Attempts at gastrointestinal antisepsis and alteration of the media to restrict bacterial pullulation yield but temporary benefit. The author has found them due in large measure to imperfect hepatic functioning, and that the best results are obtained by the administration of chologogues, and in particular, of ipecacuanha. This drug should be given in the form of the tincture, in doses at first small, then progressively increased; its use should be continued, in conjunction with careful regulation of the diet, until recovery is complete.

**Emetine in the Treatment of Hemoptysis.**—C. Flandin and E. Joltrain, in *Bulletins et Mémoires de la Société médicale des Hôpitaux de Paris*, April 11, 1913, state that they were induced to try the effect of emetine in hemoptysis through the time honored recommendation of ipecac in this condition and owing to the antihemorrhagic of emetine recently observed in cases of dysenteric liver abscesses, in which the pus was found to lose its bloody appearance after the very first injection of emetine. A young man was taken rather suddenly with a paroxysm of coughing during which a bowlful of blood was expectorated. In spite of rest, ice, and calcium chloride the hemoptysis continued, less abundantly, on the following day, and on the third day, when the patient attempted to rise from bed, more blood was brought up. Dyspnea became marked, and the temperature rose to 40° C. (104° F.). The same measures as had been employed before, together with ergot, brought some relief, but in the evening of the next day another abundant evacuation of blood took place, causing asphyxial phenomena and leaving the patient very pale. A subcutaneous injection of 0.04 gramme (two thirds of a grain) of emetine hydrochloride was given, and all other measures stopped. Bloody expectoration ceased completely and permanently, the temperature remained low, and the general condition improved. While the authors cannot definitely affirm that there was not a coincidence in this case, they point out that it is exceptional for a copious
hemoptysis to cease abruptly and for the sputum to be entirely free of blood in the days succeeding its arrest. The emetine treatment would appear to be worthy of further trial in this condition.

Treatment of Senile Neurasthenia.—R. Oppenheim, in Progrès médical for April 12, 1913, states that neurasthenia in the elderly or aged is most frequently dependent upon intoxications, including autointoxications, upon arteriosclerosis, and upon renal insufficiency. It is not enough, however, to place an old arteriosclerotic or nephritic patient upon a milk diet or a salt free vegetarian diet, if the physical asthenia, mental discouragement, excessive nervous irritability, and insomnia are to be relieved. The treatment directed against the cause of the condition must be supplemented by certain special measures. Thus, the anorexia often existing with these patients should be overcome and care taken that they ingest sufficient food. If necessary, to arouse the appetite, the following mixture may be ordered:

R. Tinctura condurango, ..........ss (15 grammes);
Tinctura gentiane, ..........aa 51s (10 grammes);
Tinctura calumba, ..........aa 51s (10 grammes);
M. Sig.: Twenty drops in water a quarter of an hour before each meal.

Or.
R. Tinctura condurango, ..........xxx (2 grammes);
Syrupur aurantii, ..........sv (120 grammes);
M. Sig.: One tablespoonful in half a tumblerful of water before meals.

Insomnia should be overcome, if practicable, by simple measures alone, such as light evening meals, lukewarm affusions or hot partial baths (avoiding full baths in arteriosclerosis especially). If such means fail, some of the least harmful sedative drugs will have to be tried, e. g.:

R. Zincii chloridi, ..........aa gr. 3. (0.005 grammes);
Valerianae, ..........aa 51s (0.03 grammes);
Extracti hyoscyami, ..........aa 51s (0.03 grammes).

Ft. in pilulae No. 1.

Sig.: One pill before supper and another two hours after.

Once or twice weekly, a cachet containing trional and perhaps heroine hydrochloride may be substituted for the second pill in the evening.

Nerve tonics should be used to combat the patient's general asthenia. Lecithin in doses of one and a half to seven and a half grains (0.1 to 0.5 gramme), either in pills or in granulated form, may be administered; or, injections of oil containing lecithin may be given:

R. Lecithini, ..........5ss (2 grammes);
Oleii olive (washed with alcohol and sterilized), ..........5x (40 grammes).

Ft. in ampullas No. xx.

Sig.: Contents of one ampule to be injected every day.

Treatment of Lymphosarcoma.—D. F. D. Turner, in a recent issue of Archives of the Röntgen Ray, reports a case of recurrent small celled lymphosarcoma in a man aged sixty-five, in which radium treatment resulted in apparent cure, already of one year's standing at the time of writing. The recurrence took the form of a swelling somewhat deeply placed below the left clavicle, and of enlarged glands in the neck, forming a mass of about the size of a small orange. A glass tube in an aluminum case containing twenty milligrammes of radium bromide was inserted into the mass below the clavicle, and a capsule containing forty milligrammes was applied daily for four hours to the glands above, and for four hours to the swelling below. A screen of silver one half millimetre thick was interposed to protect the skin from the alpha and soft beta rays. After a week the internal tube was drawn out a little by its attached thread to expose fresh tissues to its influence, and after thirteen days more, was removed altogether. Both enlargements then diminished in size. A deep glandular mass remained, however, beneath the clavicle. This was excised under anaesthesia, and a tube of radium was left in the cavity for one week. Three months later no trace of the disease could be found, and the patient had resumed his ordinary avocation.

Treatment of Furunculosis of the External Auditory Meatus.—G. Laurens, in Nouveau Remèdes for June 24, 1913, advises that a small, flexible wick of gauze be inserted in the canal and the patient be required to drop upon it every two hours a few drops of the following fluid, previously warmed:

R. Hydrargyri chloridi corrosivi, gr. 3 (0.005 grammes);
Alcoholis, ..........mm (25 grammes);
Aque destilii, ..........vi (25 grammes).

The gauze wick should be changed daily.

Hot moist compresses should also be ordered, to be placed over the whole auricular region and be renewed eight to ten times a day.

Treatment of Acute Phlebitis.—Joly, in La Clinique for March 14, 1913, asserts that the application of ice yields good results, especially in the presence of peripheral phlebitis, in inflammation of the venous walls already thickened through chronic disease, and in varicose phlebitis. Its efficacy is the greater, the earlier it can be brought into use after the onset of the acute inflammation; it may even abort the latter. As a receptacle for the ice the author uses a piece of rubber inner tube from a bicycle tire, sealed at one extremity and closed at the other with a large cork. This is placed along the course of the inflamed vein, undue pressure being avoided by suspending it from the hoops supporting the bedclothes, and immediate contact prevented by interposition of dry flannel. The rest of the extremity should be completely covered with cotton wool. Indications as to how long the ice should be allowed to remain are furnished by the effects of its temporary removal, viz., it should be reapplied whenever a painful reaction is observed to result from its withdrawal. When the local disturbance shows signs of recession, it may be left on only in the daytime, then only for a few hours several times in the course of the day.

Rectal irrigation with boiled water, cooled to 25° or 20° C. (77° or 68° F.), and with the container but slightly elevated, is also recommended by the author in these cases. The blood pressure should, however, be kept under watch. If it rises considerably, tepid or hot irrigations—30° to 40° C. (86° to 104° F.)—should be substituted for the cold.

TREATMENT OF HEART BLOCK AND OF THE STOKES-ADAMS SYNDROME.

Heart block, we may recall, is due to interference with the transmission of contractile impulses from the auricles to the ventricles. Among the causes which have been recorded, rheumatic affections of the heart, infectious diseases which tend to poison the myocardium, acute lobar pneumonia, typhoid fever, diphtheria, influenza, atheroma of the bundle of His, gumma or ulceration of this structure, and streptococcus endocarditis, occupy a prominent place. Of great clinical importance, however, in view of the freedom with which digitalis is used in practice, and the large doses that some internists advocate, is that this agent is a prolific cause of heart block. So prominent a position does digitalis occupy in the etiology of this condition in fact, that Meyer (Deutsches Archiv für klinische Medizin, civ. Nos. 1 and 2) was led to conclude through experience gained in personal cases that as compared to organic lesions such as the above mentioned, digitalis was seldom the cause of heart block. This emphasizes, besides the need of care and watchfulness in the use of digitalis, the importance of establishing clearly whether true heart block is present in a given case or whether the patient is suffering in addition from the phenomena which make up the Stokes-Adams syndrome, for while digitalis is useless and may prove harmful in the former disorder, it is sometimes of great benefit in the latter.

A clinical distinction between the two conditions in point thus becomes necessary. Roughly speaking, while heart block manifests itself by prolongation of the interval between the auricular and ventricular systoles, dropping of an auricular systole, or of every second, third, or fourth beat, or again by complete dissociation between the auricular and ventricular beats—all with slowed pulse, sometimes down to 30 and lower in threatening cases or complete heart block—the Stokes-Adams syndrome includes among its more salient phenomena, besides the slow pulse, vertigo, loss of consciousness of heart block: epileptoid attacks and visible auricular pulsation of the cervical veins. With Lewis, therefore, we should recognize that heart block and the Stokes-Adams syndrome are not synonymous terms—as taught in some textbooks—the main distinctive feature of the latter being epileptoid attacks.

In simple heart block, then, we should avoid digitalis and place our confidence in atropine which is often effective in counteracting the block by paralyzing the vagal terminals. Where syphilis is suspected as a cause, mercury or the iodicides should be tried, the salicylates in rheumatic cases. The iodicides when arteriosclerosis prevails, etc. Briefly, the cause should be carefully sought and removed where possible. Overexertion and violent emotion are very dangerous in such cases. In the Stokes-Adams syndrome, the myocardium seems, on the other hand, to demand additional tone. This is best met, in addition to treatment of the original cause, by means of strychnine. In some cases, particularly when there is dilatation, digitalis in moderate doses, or a good fluid extract of cactus grandiflorus, in thirty drop doses, as advised by Wilcox, is to be preferred. Sodium citrate and sodium iodide have been found beneficial by some observers. Hypodermoclysis and the intravenous use of saline solution—but without epinephrin, which would aggravate the block—suggest themselves as valuable aids in the treatment of threatening cases, owing to the diminished viscosity and the enhanced osmotic properties of the blood it would insure.

NITROGENURIC DIABETES.

Although this affection, termed by the French diabète azoturique, was first described by Willis (in 1858), it has received but little attention except from the French, among whom the names of Lancereaux, Bouchard, Lecorche, Demange, and Richardière
may be mentioned. Cases of it are liable to be met with occasionally, however, by all practitioners of extended experience, and it is therefore deserving of serious attention. It appears to be a special and extremely grave variety of diabetes insipidus, and its characteristic feature is the excessive amount of urea, as well as of uric acid and nitrogenous extractive substances, excreted in the very abundant urine. It is generally described as a disease of adult life, though, according to Lecorçé and others, it occasionally occurs in childhood. In this country cases are sometimes met with, especially in children, in which the azoturia alternates with glycosuria; an occurrence to which none of the French writers seem to refer. In some instances also albuminuria is noted, and cases of this kind have been mistaken for Bright's disease. Richardière mentions one case in which the patient, in the last days of life, had an intense albuminuria and succumbed to uremia.

The urine is markedly acid in reaction, and the amount of urea excreted in the twenty-four hours varies from forty to 150 grammes. The urinary salts, the chlorides and phosphates, are also increased, and the extractive matters to an enormous extent. On standing, the urine is apt to quickly assume an ammoniacal odor. In regard to some of its other characteristics writers seem to differ. Thus, Richardière states that it is of a dark (foncé) yellow, with a specific gravity which often exceeds 1.040, or even 1.050; while Jeanselme reports it as generally pale. Probably the color and density vary greatly in different instances and at different times, and it may be mentioned that observers here have sometimes found the specific gravity extremely low. The onset of the malady is abrupt in some cases and insidious in others. Once established, it for the most part presents a clinical picture quite similar to that met with in fatal diabetes mellitus. The general symptoms, the complications, and the progress of the disease are almost identical in the two affections, though Jeanselme asserts that the thirst, pronounced as it is, is less intense than in glycosuric diabetes. In all the patients observed by a prominent clinician here there was also an absence of itching.

The prognosis is invariably bad, as death is the regular termination of the disease. It should be noted, however, that Boucard is said to have observed certain instances of chronic azoturia, without polyuria, in which the prognosis was less grave, and recovery frequent. As to the etiology, nothing definite is known. Leprquois says that azoturic diabetes implies a nervous predisposition and almost always une cause occasionelle émotive, such as mental distress of any kind. In some cases alcohol has been thought to be responsible for the trouble and in others, repeated pregnancies, while cerebral tumors and other lesions, as well as those of the cerebellum and medulla, have sometimes been credited with a direct causal agency. In a few instances recovery is said to have resulted from the effect of intercurrent febrile diseases, but such a happy outcome must be too rare to be seriously considered, and in general an acute febrile disease would be much more likely to snuff out the patient's life than it would be to cure him.

While the French have principally studied this affliction, and certain English observers have devoted some attention to it, the first contribution to the subject by a writer in the Western hemisphere is a paper which was read by Dr. Anthony Bassler at the last meeting of the Medical Association of the Greater City of New York, a report of which will be found in our Proceedings on page 990. Doctor Bassler discards the term diabetes in this connection, preferring to use the word azoturia alone, and suggests the following classification: 1. Physiological azoturia. 2. Azoturia simplex. 3. Azoturia gravis.

We would suggest, however, that the French word azote means nitrogen, and that the equivalent for diabète azoturique, therefore, is "nitrogenic diabetes," the term used in our heading.

**TUBERCULIN AS A CURE OF PROGRESSIVE PARALYSIS.**

The complex processes in human pathology now and again receive fresh emphasis when a remedy employed empirically and apparently against all reason happens to modify certain pathological conditions. From our knowledge of the nature of mental diseases we should fail to understand how typhoid fever, smallpox, pneumonia, pleurisy, scarlet fever, and other acute infections can so modify the pathological changes in the insane as to bring about recovery in some cases, and marked improvement in others. Yet such results have been reported by careful clinicians, as Kelp, Girara, Holzer, Sponholz, Wagner, Leidesdorf, Friedler, Weber, Krafft-Ebing, and others. Urman reported three cases of the tabetic form of progressive paralysis in which a lasting remission followed a local suppuration. Ovorokoff reported four cases of insanity permanently improved, two while afflicted with pulmonary tuberculosis, and the others following an attack of typhoid fever. In view of the apparent favorable effect of infectious diseases on nervous and mental disorders, Wagner, of Vienna, attempted to treat progressive paralysis with bacterial toxines. At first he employed the toxines of

THE EXPERIENCE OF THE MEDICAL PROFESSION OF TORONTO IN THE TREATMENT OF SYPHILIS WITH SALVARSAN.

As announced in our issue of September 20th, No-guchi obtained from animals, infected with rabies, what appear to be cultures of an organism that, in the test tube, give rise to bodies resembling protozoa, and similar to those found in the brain of the rabid animals. It would seem that such reports from these two different sources tend to support quite firmly the theory, that the Negri bodies are the infecting agent and are a form of protozoa.

THE EXPERIENCE OF THE MEDICAL PROFESSION OF TORONTO IN THE TREATMENT OF SYPHILIS WITH SALVARSAN.

In the course of this article, D. King-Smith refers, in the Journal of Cutaneous Diseases for September, to the interesting work done by George S. Strathy, at the Sick Children's Hospital, on congenital syphilis. His observations are as follows: 1. A negative history in a mother is of little value. 2. In the smallest babies blood may be obtained for a Wassermann test by puncturing the median basilic or cephalic vein, or if they cannot be located, then use the external jugular vein. 3. In nursing babies indifferent results are obtained by treating them through the mother. Small doses of either salvarsan or neosalvarsan may be injected into the jugular vein. These small doses are repeated twice a week until a negative reaction is obtained. In babies better results are obtained by salvarsan and neosalvarsan than by mercury. 4. In children salvarsan is to be preferred to neosalvarsan. 5. In children, at first, the dose of salvarsan should be reckoned according to body weight, using as a standard 0.6 gramme of the drug for each 150 pounds of body weight. 6. In late congenital syphilis, those cases showing interstitial keratitis, etc., it is much more difficult to obtain a negative reaction.

THE DOCTOR IN COURT.

J. J. A. O'Reilly, in American Medicine for September, 1913, in concluding the second article of a series on this subject, sums up in these words: Let us, then, as members of this sacred profession of ours, seek to develop a personality which will win the respectful attention of the people and the courts; let us try to realize and fulfill our duty to judges, juries, and parties, as well as to the State; let us by every means possible amplify our knowledge and experience, and use these instruments honestly and fearlessly in our analysis of all medicolegal propositions, and let us at all times be on the watch for the danger signs which beset our own path. Finally, let no unworthy interpretation of a "code of ethics" prevent our alliance with justice in an effort to restore to our profession the respect and dignity which belongs to it in this highly important branch of its application, the giving of expert testimony.

the pyocyanus bacillus, but it proved unsatisfactory, owing to the uncertain dose and severe reactions in some cases. The use of old tuberulin proved very much safer and more effective. The results he and his followers obtained are really remarkable, considering the hopelessness of the affection. Thus Piclz reported eighty-six cases of paralysis with improvement in 23.2 per cent, marked improvement in 10.44 per cent. and recovery in 26.92 per cent. Since 1911, N. A. Zhukoff (Roussky Vratch, June 15, 1913) employed tuberulin in sixty-four cases of progressive paralysis and obtained improvement in 26.55 per cent, and very marked improvement, in the effect of such a case, in 26.56 per cent. Just how the toxins act in these cases we do not know. Evidently, some profound impression is made on metabolism, affecting the nervous system. It is quite certain that, like drugs, toxins exert a double action, a direct specific action on the cells concerned in the production of specific immunity and a general action on the system. Whether it is the latter effect that is productive of favorable results in certain nervous conditions is still a matter of conjecture. At any rate, it is an interesting observation in neuropathology and therapeutics and should be subjected to further study.

QUININE AND RABIES.

That rabies can be prevented by the administration of the Pasteur treatment is a well recognized fact. But it has certain weak points. It must be employed before the infective agent of rabies has had opportunity to develop. Then, too, it requires some days before protection can occur in the inoculated person. If the patient has already developed symptoms of the disease nothing is gained by using Pasteur's method.

Inasmuch as rabies is an infectious disease, a living agent of some description must be present. By many observers this is thought to be protozoan in character. With this as the basis of his work, Moon tried out the action of quinine on dogs that were inoculated with rabid brain material and were allowed to develop active symptoms of rabies. Quinine was then administered internally in large doses, equivalent to from twelve to eighteen grammes daily for an average man. The medication was pushed to the limit to secure the full physiological effect, one bordering on the toxic. As a result three untreated animals died, while the three treated ones recovered. Report also comes that this method has been employed successfully in one case of a human being.
Obituary.

CHARLES MCBURNNEY, M. A., M. D.,

of New York.

Dr. Charles McBurney died on November 7, 1913, at the age of sixty-eight years. He was graduated from Harvard University in 1866, and from the College of Physicians and Surgeons, of New York, in 1869. After studying abroad he joined the staff of the College of Physicians and Surgeons in 1872, becoming professor of surgery in 1889, and retired in 1907 on account of ill health.

The death of Dr. Charles McBurney removes from the medical profession of the United States a man who during his active career did as much to develop the science and art of surgery as anyone of his time in America. He was one of the first to adopt aseptic methods and to improve and simplify them. The aseptic operative technic devised and practised by him in the Roosevelt Hospital of this city, and is, a model which has scarcely been improved upon during the last thirteen years since he left that institution.

The details of the modern steam sterilizer, now in general use with but slight modifications, were worked out in the Roosevelt Hospital by him and by Dr. Frank Hartley. Mr. Sprague was the engineer who furnished the mechanical skill to accomplish the object in view.

Dr. William S. Halstead had urged the use of rubber gloves in operations; but much credit is due to McBurney in this regard, who, by painstaking experiments, showed to the world that rubber gloves were not only advisable, but necessary for the surgeon and for the entire personnel of the operating room who handled anything which might come in contact with the wound. His method of sterilization and the use of dry gloves, with armlets, has now become general, though not until many years after he demonstrated the advantages of that method.

Doctor McBurney's fame among the laity seems to rest chiefly on a few things. First upon his so called "point" in the diagnosis of acute appendicitis and his skill in operating for that disease. Upon the latter he really prided himself, and very justly too. Less well known to the general profession was the devising of the intermuscular incision for removing the vermiform appendix. A third impression, derived I know not how, seems to be that his greatest skill lay in the treatment of accident cases. The most important part of his work in relation to appendicitis is perhaps not so well appreciated, namely, what he did to convince the medical profession that acute appendicitis was purely a surgical affection requiring immediate surgical care, and this he did by constant effort in his clinics, "precept upon precept, line upon line." It may not be generally known that, clever though his intermuscular incision was in its conception and execution, he for many years feared to use it in acute cases, lest drainage be imperfect, and only after its efficiency for nearly all cases had been demonstrated by other surgeons did he adopt it in his own work, except in the simpler forms of the disease.

The man was, however, a much broader, wiser, and more skilful surgeon than those who knew him only by reputation thought. He was a surgical diagnostician whose equal I have scarcely met, and yet his methods of examining cases were simplicity itself. His judgment as to when and how to operate I have never seen equaled. His operative technic was painstaking, accurate, and remarkable. In that the least possible injury was done to the tissues in order to accomplish the desired result. Each step was orderly and progressive. *Nulla vestigia retrorsum* was a prominent characteristic. No field nor procedure was gone over twice. As a consequence, the convalescence of his patients was unusually rapid, and they suffered a minimum of shock.

McBurney's intellect was quite superior to that of the average surgeon. When confronted by a difficult surgical problem, he was able to devise on the instant some new and entirely original procedure for overcoming the obstacle, and many were
the permanent advances in surgical technic he made at the operating table. Many of these have become permanent and valuable standard methods. To mention only a few: A small transperitoneal incision for the purpose of compression of the common iliac artery by the fingers of an assistant during disarticulation at the hip joint; McBurney's transduodenal method of removing stone from the common bile duct in certain cases; McBurney's hooks for skin grafting; McBurney's tractor or hook for the reduction of fracture dislocation at

the shoulder joint; McBurney's staff, with a combined gorget and knife for rapid perineal section. This list might be greatly lengthened, but will suffice to indicate some of the characters and the readiness of his splendid intellect.

As a teacher and lecturer, McBurney was simple, clear, and eminently practical. He believed that in his clinical teaching it was better to speak of a few common and important things, and to teach them thoroughly, rather than to operate upon and discuss in public the rarer conditions and the more difficult procedures such as most of his hearers would never themselves undertake. As a consequence, in his public clinics, he often elected to do quite simple operations and to repeat them frequently. Among his favorite operations were amputation of the breast for carcinoma, hernia, and resection of the knee for tuberculosis. The more difficult and rarer cases were often operated upon on days when the public were not expected to be present.

In his relations with the house staff of the hospital he was always absolute master. His slightest hint was a command not to be disobeyed. The younger men regarded him almost as a superior being, and if they did their work well he treated them with the utmost kindness.

To his patients he was gentle, self-sacrificing, sparing himself not at all. His manner was always charming, and I have never seen a sweeter smile on any human face than he did show. He inspired absolute confidence in those under his care. His winning manner, absolute devotion to duty, and superior intelligence aroused in those who worked with him professionally the highest admiration, affection, and esteem.

"He was a man, take him for all in all.
I shall not look upon his like again."

ALEXANDER B. JOHNSON.
News Items.

Changes of Address.—Dr. Nathan S. Rawdin, to 1000 Fox Street, the Bronx, New York, N. Y.

Personal.—Dr. H. Sheridan Baketel, of New York, and Dr. Robert I. Bull and Dr. Philip M. Schaffner, of Brooklyn, have been appointed instructors in ophthalmology and otolaryngology at the University of Nebraska. Dr. E. Davis Friedman, Dr. John H. Wyckoff, and Miss C. Sturtevant have been appointed instructors in medicine at the University and Bellevue Hospital Medical College.

Dedication of New Medical College in Omaha.—The new college of medicine of Nebraska University was formally opened on Thursday, October 16th. Dr. Howard A. Kelly, professor of gynecology at Johns Hopkins University, delivered the principal address.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, November 17th, Philadelphia Clinical Association, Medical Society of the Woman's Hospital, and the Episcopal Hospital Clinical Society; Tuesday, November 18th, West Branch of the Philadelphia County Medical Society and the Laryngological Society; Wednesday, November 19th, Section in Oto-laryngology of the College of Physicians; Thursday, November 20th, Section in Ophthalmology of the College of Physicians, Northeast Branch of the Philadelphia County Medical Society, and the Pathological Society; Friday, November 21st, Southeast Branch of the Philadelphia County Medical Society.

Pellagra in Pennsylvania.—Physicians throughout the State of Pennsylvania are much interested in a case of pellagra in the household of a woman in Chester on Friday, October 31st, and in another case recently reported in Lancaster. According to health reports of the State Department of Health, thirteen cases have been reported throughout the State, as compared with three in the same period last year, and one in the previous year. These are the first cases of pellagra reported in Pennsylvania in ten years, and physicians are much mystified as to the cause of the sudden outbreak. An investigation is to be made by a Department of Health medical examiner to be left undone to check the further spread of the disease.

Medical Association of the Greater City of New York.—A stated meeting of this association will be held in Du Bois Hall, New York Academy of Medicine, on Monday evening, November 1st, at 8 o'clock. The program will include the following papers: The Importance of Early Recognition of Myopathies by the General Practitioner, by Dr. Francis A. Scratchley; Why Electricity Does Not Cure, by Dr. Albert C. Geyer; X Ray Diagnosis of Gout, by Dr. Frank W. Robertson; and Doctors Geyser, by Dr. William B. Pritchard, Dr. Frank W. Robertson, Dr. David E. Hoag, Dr. William Van Pelt Garretson, and Dr. J. Victor Haberman. Doctor Friedman will be the chairman, as illustrated by lantern slides.

Southern Medical Association.—The seventh annual meeting of this association will be held in Lexington, Ky., on Tuesday, Wednesday, and Thursday, November 18th, 19th, and 20th, under the presidency of Dr. Frank A. Jones, of Memphis, Tenn. An excellent program has been prepared, which includes symposia on the cancer problem, vaccine therapy, malaria, pellagra, the milk question, uncertainty, vital statistics, and the negro in relation to public health. Among the special features of the meeting will be the organization of the Southern Association of Railway Surgeons, and the first annual conference of the public health officials of the sixteen Southern states. An elaborate programme of entertainments has also been arranged, and the meeting gives promise of being of more than ordinary interest, as it is the first that over one thousand physicians will be in attendance. The officers of the association are: President, Dr. Frank A. Jones, of Memphis, Tenn.; first vice-president, Dr. Stuart McGuire, of Richmond, Va.; second vice-president, Dr. J. D. Love, of Jacksonville, Fla.; secretary-treasurer, Dr. Seale Harris, of Mobile, Ala. The chairman of the four sections are as follows: Section in Medicine, Dr. Graham E. Henson, of Jacksonville, Fla.; Section in Surgery, Dr. W. A. Bryan, of Nashville, Tenn.; Section in Ophthalmology, Dr. U. S. Bird, of Tampa, Fla.; Section in Hygiene and Preventive Medicine, Dr. J. Y. Porter, of Jacksonville, Fla.

American Academy of Ophthalmology and Otolaryngology.—At the annual meeting of this association, held in Chattanooga, Tenn., recently, under the presidency of Dr. John W. Murphy, of Cincinnati, the following officers were elected: President, Dr. M. Ray, of Greensboro, N. C.; first vice-president, Dr. J. M. Ingersoll, of Cleveland, Ohio; second vice-president, Dr. C. B. Wylie, of Morgantown, W. Va.; third vice-president, Dr. D. C. Loughery, of Charleston, W. Va.; secretary, Dr. W. B. Bufalo, N. Y.; treasurer, Dr. S. H. Large, of Cleveland, Ohio; councilors, Dr. Allen Greenwood, of Boston, and Dr. Samuel Ingrazier, of Cincinnati. Next year's meeting will be held in Boston.

New York Academy of Medicine.—The following programme has been arranged for a meeting of the Section in Medicine of the New York Academy of Medicine, to be held on Tuesday evening, November 18th: Dr. E. C. Rosenow, of Chicago, will read a paper on the Relation of the Lesions Produced by the Members of the Streptococcus Group, with Special Reference to Endocarditis and Rheumatism, which will be followed by a demonstration of specimens. Dr. E. Libman, of New York, will present a paper on the Clinical Feature of Tuberculous and Syphilitic Rheumatism (Chronic Subacute Endocarditis, Endocarditis Lenta) in the Bacterial Stage, and will exhibit specimens of the various forms of endocarditis. These papers will be discussed by Dr. Rufus I. Cole, Dr. E. M. Evans, Dr. L. T. Connor, Dr. J. A. Balfour, and Dr. L. M. Augustus Wadsworth, Dr. W. Thalheimer, and Dr. P. Aschner. At the close of the meeting the nomination of officers for 1914 will be held. Dr. Linsly R. Williams is chairman of the section and Dr. Joseph C. Roper is secretary.

Gettysburg Dinner of the Medical Reserve Corps.—The annual dinner of the New York Division of the association of the Medical Reserve Corps, United States Army, was held at the Hotel Savoy, New York, on Tuesday evening, November 18th, the eve of November 19th, twice a week, with the following officers of the regular corps: Colonel L. M. Maus, chief surgeon of the Eastern Department, Lieutenant Colonel A. E. Bradley, Major A. E. Truby, Major J. F. Russell, Major H. L. M. Little, and Lieutenant H. Rutherford. Dr. T. H. Hess, Lieutenant Henry C. Coe acted as toastmaster. Surgeon General Charles F. Stokes, United States Navy, responded for his branch of the Service, and explained the medical side of naval warfare, especially as it has to do with members of the Naval Medical Reserve Corps. Dr. Simon Baruch, late professor of hydrotherapy in the College of Physicians and Surgeons, Columbia University, and a surgeon in the Confederate Army, gave some delightful reminiscences of his experiences during the war. Colonel Bradley compared the facilities of the medical officer of 1863 and 1913, and also gave an enlightening picture of the army's medical department from 1775 to date. This dinner was in commemoration of the service of twenty-four members of the Medical Reserve Corps at the recent encampment in Gettysburg of Union and Confederate veterans, commemorating the fiftieth anniversary of the Battle of Gettysburg. In this connection, Lieutenant Thomas Darlington and Lieutenant Reuben Wohlf was gave their experiences as medical officers at the encampment. Major James E. Normyrole, of the Quartermaster Corps, who was chief quartermaster in charge of the encampment at Gettysburg, and who was also in charge of the commissioned doctors in the army, reviewed the proceedings of the conferences following the floods last spring, gave a graphic description of the work of preparing the great encampment for the veterans, and paid high tribute to the efficiency of the fifty regular and reserve medical officers and 150 working men. The dining room was crowded and demonstrated the strong position which the Medical Reserve Corps in New York has assumed. The officers present represented the medical faculties of the College of Physicians and Surgeons, Cornell University, College of Medicine and Cornell Medical College, Long Island College Hospital, and the Post-Graduate and Poly-clinic Medical Schools. The designation for officers for 1914 is as follows: President, Lieutenant Henry C. Coe; vice-president, Lieutenant Dr. Roydon Wohlf; treasurer, Lieutenant H. Sheridan Baketel; councilors, Lieutenant Howard Lillian, Lieutenant Howard Fox, Lieutenant W. M. Bricker, Lieutenant J. H. Lawson, and Lieutenant S. M. Strong.
Pathogenesis of Psoriasis.—A. Leroy assigns to the subsquamous membrane discovered by Bulkeley in the lesions of psoriasis the rôle of a dialyzer, separating from the lymph and blood serum various dissociation products of the albumins and eliminating them in the form of a serous fluid. The foreign fats and lipoids described by Abderhalden in the blood may also be involved in such a process, and the author is convinced that the microorganisal theory of Unna and his followers should be abandoned in favor of the older theory of "peculant humors." Clinical and histological evidence is advanced in favor of this view. Oil of cade and similar drugs act by hardening and obstructing the dialyzing membrane.

Treatment of Hemicheora.—G. Ravarit reports a case of hysterical chorea limited to one side of the body, and another of similar hemicheora in a highly neurotic individual. Both patients were young girls. In each instance the ordering of a salt-free diet, without the administration of drugs of any kind, appeared to play an important part in the patient's recovery.

Gastroenterostomy with the Aid of Jaboulay's Button.—Huguiér and Rigollet-Simonnot recommend the use of Jaboulay's button in all cases in which posterior gastroenterostomy is practised in association with another operation, such as pyloric exclusion or gastrectomy; where the patient's general condition demands brevity of operation; where the stomach cannot well be delivered through the incision owing to adhesions or a tumor; and finally, where this organ cannot be satisfactorily evacuated, as in bleeding ulcers and in cases too cachetic to stand gastric lavage. Jaboulay's device differs from that of Murphy in that each of its halves is introduced into the corresponding viscus by a rotary motion through an opening only about eight millimetres long made with the thermocautery. No suturing of the button is required unless the incision has been made too long. Rapidity, asepsis, and perfect hemostasis are insured with this button, which, in the author's experience, has always proved wholly satisfactory except in a single case in which it remained in the stomach. Without, indeed, the patient's experiencing any trouble therefrom. Fluids are allowed on the second day and a liquid diet subsequently until the tenth, when the button becomes detached. No vomiting takes place after operation, fluid in the stomach passing at once into the intestine.

Cobra Venom Activation Test in Mental Diseases.—M. Klippel and M. P. Weil applied in mental diseases a test, already investigated in tuberculous by Calmette and others, which demonstrates the presence or absence of lipoids or fatty acids in any fluid examined. To each of a series of five test tubes containing graded amounts—from 0.1 to 0.5 c. c.—of the serum of the patient under examination was added 0.5 c. c. of a one in 5,000 solution of cobra venom and 0.1 c. c. of a twenty-five per cent. emulsion of thrice washed and centrifuged red corpuscles of a rabbit. Saline solution was then added to bring the volume of fluid in each tube up to three c. c., control tubes without cobra venom prepared, and the whole series examined every five minutes for two hours and again at the end of twenty-four hours. In a positive test, hemolysis occurs, the hemolytic property of the cobra venom, otherwise not exercised, being activated by the lipoid or fatty acid present in the fluid examined. The serum of twenty-two out of thirty-five cases of general paralysis, i. e., 62.8 per cent., and that of seventeen out of twenty-three cases of dementia precoex, i. e., 73.9 per cent., gave a positive reaction. The positive results are attributed to the disintegration of nerve tissue taking place in these cases. The negative reactions among the paretics were uniformly in patients already in an advanced stage of disease. Unfavorable prognostic significance is ascribed to a negative reaction in dementia precoex as well as in paresis, such a reaction signifying that the brain has already yielded to the blood all the lipoids it can dispose of. In alcoholic mania and Korsakow's syndrome.
strongly positive reactions were noted, while in psychoses of depressive type negative results were the rule.

REVUE DE CHIRURGIE.

September, 1913.

Freund's Theory and Operation in Pulmonary Emphysema.—S. Roubachow considers Freund's work and views as to the relationship to lung emphysema of a rigid thorax with abnormally low expansibility of great import, but objects to that part of his theory which attributes this low expansibility exclusively to disease of the costal cartilages. In studies of the cartilages in 330 cadavers the author found that while among emphysematous subjects the percentage showing ossification of these cartilages is greater than in normal subjects of the same age, there is no histological difference between the cartilages in the two groups of individuals. Neither the location nor the extent of the ossification is characteristic of emphysema; contrary to Freund's statements, changes in the periphery of the rib cartilages are not typical of emphysema, occurring as well in non emphysematous old subjects. Measurements of the length of the cartilages—numbering 175—revealed no difference between the emphysematous and non emphysematous. Besides, the torsion of the cartilages and the widening of their angle with the sternum are not accounted for by the exclusively chondral theory of emphysema. In spite of all this, Roubachow strongly favors the performance of Freund's operation of cartilage resection in many cases of emphysema. Among eighty patients operated upon, twenty-five showed relief lasting a year or more; twenty-six were relieved but escaped from observation in less than a year; six were improved only temporarily; four were improved only after an interval had elapsed since the operation; six were unimproved, and nine died. From a study of the fatal cases the author considers as relative contraindications to the operation: Severe purulent bronchitis, bronchiectasis with profuse expectoration, lung tuberculosis, asthma, heart disease, very marked arteriosclerosis, and extreme old age. The presence of a dilated but not rigid thorax, or of a very advanced stage of emphysema, is an absolute contraindication. In other cases the operation is a safe one. Roubachow favors removal of large sections of cartilage—of four to six centimetres—and lays stress on the fact that to procure full benefit from the procedure mechanical respiratory gymnastics, Hofbauer's method of expiratory stimulation, etc., must follow.

Primary Carcinoma of the Jejunum.—A. Venot and A. Parceiller, in a study of thirty-six operated cases of cancer of the jejunum or ileum, found that in the ten cases in which resection of the diseased bowel was performed in the presence of obstruction the mortality was seventy percent, while in sixteen cases in which the same procedure was carried out in the absence of obstruction it was only 18.7 percent. Of the ten remaining patients, subjected to a palliative operation only, the high mortality, sixty per cent., is accounted for by the more serious condition of these patients. Resection is the operation of choice where obstruction does not exist, and yielded complete cures, confirmed by subsequent autopsy, in two cases, as well as almost certainly in a third, under the care of Mikulicz, still living over seven years after the operation. Free excision beyond the diseased portion of the bowel should be practised, especially above. Adhesions rarely contraindicate resection. Multiple foci of disease contraindicate it where the length of gut to be excised would have to exceed three metres. Even where lymphatic involvement extends high up in the mesentery the operation need not be given up, as a wedge-shaped piece of mesentery can be removed, or even ganglia situated upon the spinal column taken out, as in the personal case of the authors. Diffuse malignancy contraindicates resection, but not the mere presence of nodules on the neighboring intestinal serosa or the mesentery. In cases with obstruction enteronastomosis as a palliative operation is far superior to enterostomy, the employment of which should be restricted to patients whose general condition contraindicates all other measures. Enteronastomosis has prolonged life for from a few to fourteen months.

Surgery of Spinal Tumors.—Potel and Veaudue, concluding a detailed exposition of this subject begun in the May issue, assert that whereas the mortality of operation for spinal tumor only a few years ago averaged forty-five per cent, it is now only fifteen per cent. Statistics bearing on the last ten years show fifty-eight per cent. of recoveries. Recurrence of a spinal tumor is not as likely to occur as in other parts of the body, spinal sarcoma and fibro-sarcoma being relatively benign.

REVUE DE MEDECINE.

September, 1913.

Epileptic Dementia.—R. Benon and A. Legal assert that this condition has not as yet been given sufficient consideration from the clinical standpoint by medical writers, and summarize the results of their personal studies as follows: True epileptic dementia is characterized by a more or less slowly progressing partial weakening of the intellect, affecting the memory, attention, imagination, and the powers of judgment and reasoning, and associated with affective changes and diminished general activity. Beside these primary mental deficiencies there are often observed delusions, periods of mental confusion, asthenia or hypersthenia, dysarthria, etc. The condition may be divided into several forms: 1. A common form; 2, special forms differing from the ordinary type as regards the course of the affection—rapid, slow, and remittent forms; 3, special forms based on certain symptoms—pseudoparalytic, asthenic, maniacal, paralytic, and spasmodic forms. Epileptic dementia must be clearly distinguished from the other psychic disturbances witnessed in epileptics. From the exclusive standpoint of dementia it must be differentiated from idiocy, imbecility, mental debility, dementia precoex, paralytic dementia, and senile dementia.

Treatment of Tuberculosis.—A. Krokiewicz reports the results obtained in a large series of tuberculous cases by the administration of pills and the subcutaneous injections of antisepic drugs, alternatives, tuberculin in small amounts, etc. Of the pills used, two hundred were prepared from the following ingredients: Eucalyptol, two grammes;
magnesium oxide, 2.5 grammes; pure crystalline calcium chloride, 1.5 grammes; potassium guaiacol-sulphonate, ten grammes; quinine hydrochloride and phenyl salicylate, of each five grammes; and menthol, one gramme. Two pills were given after each meal. The two solutions for hypodermic injection, of which two c. c. were given alternately at four day intervals, were as follows: (I) Thymol and sodium cinnamate, of each 0.02 gramme, dissolved in fifty grammes of hot water, to which, after cooling, are added novocaine and atoxyl, of each 0.25 gramme; gujasanol (diethylglycolguaiacol hydrochloride), five grammes; dry tuberculin, 0.0001 gramme; sodium chloride, 0.5 gramme, and sterile distilled water, enough to make 100 grammes (to be filtered). (II) Same as solution I, but with the gujasanol and tuberculin omitted. In 103 cases of lung tuberculosis in the second stage injections averaging twenty per patient were given, together with the pills. At the termination of the treatment fifty-eight per cent, showed marked improvement, which was maintained for two years; in ninety-four per cent, the pulmonary physical signs practically disappeared, and in seventy-four per cent, the patient gained weight. In 108 cases of lung tuberculosis in the third stage, similar treatment yielded marked improvement in nine per cent, and some improvement in forty-six per cent, while after the remainder the condition grew worse during treatment. In twenty-seven cases of tuberculosis involving serous membranes, two of glandular tuberculosis, and twelve of joint and bone tuberculosis, the treatment led to improvement in a majority of instances. Hemoptysis contraindicates the injections, which should be begun only from four to six weeks after cessation of hemorrhage. The injections were always well borne, and no albuminuria was observed.

Congenital Malformations in Leprosy.—G. Barbézieux reports from Indo-China deformities of the hands and feet observed in two children—brother and sister—the offspring of leprous parents. The hands are hook shaped, and the feet bird-like, like the claws of a lobster. Neither case showed the bacilli in the nasal secretion. These and similar malformations are to be looked upon as inherited degenerative manifestations, dependent upon the leprosy in the parents, but not necessarily accompanied by leprous infection in the offspring.

Effects of Emetine on Abscess of the Liver.—R. L. Spittel's patient died as the result of the premature removal of drainage tubes after an operation to drain the abscess cavity in the liver. Prior to the operation, the patient had received emetine, and this was continued after the operation. After death it was found that the cavity, which had previously contained a pint and a half of purulent material, had been reduced to a capacity of only about four ounces. The striking feature was the extremely rapid and profuse proliferation of fibrotic tissue, which Spittel believes was attributable to the use of emetine.

Experimental Observations on the Cause of Death in Acute Intestinal Obstruction.—As the result of extensive and painstaking experimental observations, D. P. D. Wilkie comes to the following conclusions:

1. Simple obstruction of the intestinal lumen must be clearly distinguished from strangulation. In the latter, death ensues long before the obstruction to the outward passage of intestinal content has become a factor of importance. 2. Simple obstruction high up in the intestine differs from that lower down, chiefly in the great loss of fluid and electrolytes which takes place in the former, compared with the latter, where the secretions are reabsorbed above the obstruction. 3. Absorption of poisons from the content of the obstructed intestine is not the leading factor in producing the symptoms of the syndrome of acute ileus, but is in itself of allowing the content pent up above an obstruction to flood the empty intestine below has probably been exaggerated. 5. Peritonitis plays no part in causing death in the majority of cases of simple intestinal obstruction; in cases of strangulation, however, it may undoubtedly be a factor in the latter stages. 6. In all varieties of intestinal obstruction the bowel content is highly infective. 7. Splanchic paresis with depletion of the systemic circulation is the main factor in producing the symptomcomplex of acute intestinal obstruction. In treating this factor by vomiting in the former, compared with the latter, the secretions are reabsorbed above the obstruction. Copious subcutaneous infusions of saline and dextrose solutions are of immense value. Clinically, the administration of pituitrin is found to be a valuable adjunct. 8. The prompt relief given by enteroectomy in cases of simple obstruction of the small intestine in the human subject is to be explained, not so much by the relief from toxic absorption as by the breaking of a vicious circle, the intestinal distention causing a paresis of the splanchic vessels, and vice versa. By relieving the intestinal distention the splanchic vessels are allowed to regain their tone, and the depletion of the systemic circulation is arrested. 9. The operative treatment of intestinal obstruction should be as conservative as possible; only on imperative indication should the intestinal lumen be opened. The danger of a postoperative peritonitis from the slightest soilning is much greater than that of toxic absorption from a loaded bowel.

Chronic Interstitial Enteritis.—T. K. Dalziel reports upon seven cases of this hitherto undescribed condition. The symptoms are those of recurring attacks of most intense intestinal colic, associated with but slight rises of temperature, and accompanied with a boggy, puttylike feeling of the abdomen. The pathological findings were those of a chronic interstitial inflammatory process involving the mucosa and submucous tissue. The mesentery was but slightly involved, and the lymphoid tissue was almost free from abnormality. There were evidences of acute inflammation with infiltration in the earlier stages; cellular and fibrous exudation characterized the next stage; in the late stages there was a deposit of fibrous tissue, granulation tissue, and an infiltration with mononuclear cells. No bacterial flora is constantly related to the lesions, the precise etiology remaining unknown. In cases in which the entire intestine is involved the condition is fatal. Where only a portion is affected, resection of this part of the intestine has cured the patient. Dalziel suggests a possible close relation between this disease and Johnne's disease of cattle.

Neuralgia of the Twelfth Dorsal Nerve.—T. K. Dalziel says that this condition often closely simulates acute intraabdominal lesions, but can be differentiated therefrom by the absence of all the symptoms of such lesions except pain. The condition is associated with three points of tenderness: one immediately under the twelfth rib, near the outer border of the quadratus lumborum; one near the inner side of the anterior superior spine of the
PITH and women in closely constant difficult. Calculous neither all blood eral epithelium mal blood lesser blood. The ways is between arteries pullying that anuria, triutable new blackly—tween arteries, E. morbid necrosis is associated acute hemorrhages, and the majority of cases have convulsions. Where anuria is not absolute the total amount of urine excreted is always very small. The morbid lesions are constant in so far as the renal necrosis is symmetrical, and associated with thrombosis of the vessels supplying the cortex. The vascular changes differ somewhat; some being confined to thrombosis of the interlobular arteries, some of the interlobular veins, and the rest showing thrombosis of both arteries and veins. It is not possible to state the cause of the thrombosis, and the precise relation between the cortical necrosis and the vascular lesion is still open to discussion. The fact that these cases do not have the severe uremic symptoms of extremely acute nephritis is possibly explained by the fact that the products of the degenerated renal epithelium are prevented from entering the general circulation by reason of the interference with the blood supply of the kidneys. These cases characteristically do not have edema, and when this condition is present it is due to a preexisting renal lesion.

The Effect of Altitude on the Blood.—Georges Dreyer and E. W. A. Walker adduce evidence to show that, in rabbits which have been taken from low country into regions of high altitude, there is a rise in the number of red cells and the hemoglobin content of the blood to an extent of ten per cent, or more within the first twenty-four hours. This is due to a concentration of the blood. The same response is encountered in man. After several weeks, the proportion of hemoglobin increases by about twenty-five per cent. Most of the later increase in hemoglobin is due to the formation of new hemoglobin, about half of the total being attributable to this cause. The blood volume is always decreased at great altitudes over the normal for the same animal, or for man, at lesser heights. The decrease in the blood volume was found to amount to over eight per cent, in rabbits. When these same animals are returned to the original lesser altitude from which they were taken, the blood volume increases, but not quite so rapidly as it decreased at the great height, returning to normal in about four days. The hemoglobin and the red cells also return to their former normal figures for the lower region, requiring from fifteen to nineteen days for the return. The authors also find that the oxygen capacity of the blood runs exactly parallel with the changes in the percentage of the hemoglobin, being greatest when the hemoglobin is increased and vice versa. Several other interesting facts have been adduced by the authors. They find that the volume of blood for any warm blooded animal is proportional to the body surface. It may be calculated by the formula: 

\[ B = \frac{W^n}{k} \]

B is the blood volume, W the weight of the animal in grammes, n is approximately 0.72, and k is a constant which has to be determined for each species. In cold blooded animals the blood volume is neither proportional to the weight nor to the body surface; in these the percentage volume of blood actually increases with increase in the weight of the animals as they grow older. The authors also find that the sectional area of the aorta just above the semilunar valves, and of the trachea, are proportional to the body surface. The ratio between the weight of the heart muscle and the total oxygen capacity of the blood is constant from species to species. The blood volume and sectional area of the aorta are rather smaller in the female than in the male, except during pregnancy when the blood volume increases. On the other hand, the sectional area of the trachea is rather greater in the female than in the male. Inhalation of an increased amount of CO₂ leads to a prompt dilution of the plasma and an increase in the blood volume. Oxygen, on the other hand, does not alter the normal blood volume. Active vasodilatation is associated with an immediate dilution of the blood plasma and increase in the blood volume, so that it is not likely that dilating drugs can bring about any lasting reduction in the blood pressure.

Veronal Poisoning.—William H. Willcox gives a detailed discussion of poisoning by this drug in man. The symptoms after a single large dose are Headache, drowsiness, ataxia, somnolence, coma, cyanosis, pulmonary congestion with symptoms of pneumonia, and often a fever of 103° F. or more. There may also be edema of the lungs, and death may ensue in less than twenty-four hours. Digestive disturbances often occur in persons who have acquired the veronal habit, but in the experience of the author the occurrence of rashes is far less common than is generally stated to be the case. In cases of chronic poisoning there is often a decided mental change, including hallucinations and delusions, speech is often disturbed, and there are tremors. The moral sense is as greatly impaired as is the case in morphine habitues. The fatal dose may be as low as fifteen grains, but this is probably only in the presence of an idiosyncrasy. About fifty grains may be considered a dangerous dose, but more than this has been survived. The treatment of the condition is early lavage of the stomach, if the patient be seen soon enough after the ingestion of the drug. Coffee and other stimulants should be administered, and a brisk cathartic should be given. There is no characteristic post mortem lesion, and toxicological analysis is difficult. It should be remembered that the drug is rapidly excreted through the urine.
Experimental Transmission of Disseminated Sclerosis to Rabbits.—W. E. Bullock has succeeded, in four out of five rabbits, in producing paralysis of the extremities and lesions of the spinal cord which are exactly similar to those seen in man by subcutaneous injection of spinal fluid derived from human cases of disseminated sclerosis. The fluid was removed under aseptic conditions, and in one or two instances was passed through a Berlinerfeld filter before injection. These results would seem to lend some evidence to the view that disseminated sclerosis is due to a filterable virus, for, not only was it possible to transmit the disease by means of the filtered fluid, but in no cases did the injected rabbits develop symptoms in less than fourteen days after inoculation.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

The Pseudodiphtheria Organism in the Urinary Tract, by W. W. Townsend.—See this Journal for July 5th, p. 49.

Correction of Impediments of Speech in Our Public Schools.—H. F. McBeath recommends a treatment consisting in bringing to a state of perfection, in the order named, the acts of respiration, phonation, and articulation. It having been ascertained that the patients will be benefited by the application of the principles advised, there is no reason why they may not be entrusted to a specially instructed teacher, as it does not require a mind with the technical training of the physician to comprehend these principles. That the stammerer can be successfully handled in the public school there is no question. What is needed is the cooperation of the medical profession in encouraging the installation of a department for the correction of impediments of speech, to see that teachers for such departments receive proper training, and to furnish school boards with information regarding the stammerer.

The Surgery of Infantile Paralysis.—E. W. Ryerson calls attention to some of the more useful operations applicable, which have stood the tests of time and experience, and expresses the opinion that in general far too little surgery is done in cases of infantile paralysis, and that nearly all cases can be improved by operations properly planned and executed.

Acidosis as a Complication after Surgical Operations.—W. B. Russ has collected the records of thirty-four cases, in seven of which a fatal issue resulted, and concludes that because of a marked reduction in the normal alkalinity of the blood, the result of some perversion of metabolism, many of the patients requiring surgical operations are unfit subjects for general anesthesia and the ordeal of an operation. The warning signs in such cases are (1) a history of unexplained headaches, vertigo, dyspepsia, occasional nausea or vomiting, an unreasoning dread of the operation, and tachycardia and other nervous symptoms; (2) a peculiar sweetish odor to the breath, suggesting the smell of rotten apples—in some cases marked and unmistakable; (3) the presence of acetone bodies in the urine. A recognition of acidosis in time, with the institution of such measures as a carbohydrate diet of, say, from six to eight ounces of oatmeal and cream with lactose, the use of large quantities of carbonated alkaline water and colon flushings with an alkaline solution, and the internal administration daily of three or four drachms of sodium bicarbonate or citrate by the mouth, will be followed by the rapid disappearance of all or most of the unfavorable symptoms.

A Case of Tumor of the Hypophysis Partially Removed by the Transfrontal Method of Approach.—This case is reported by C. H. Frazier and J. H. Lloyd, and in concluding the account of the operation Doctor Frazier emphasizes the many advantages which the transfrontal operation has over the transsphenoidal methods. The facility of exposure, the opportunity of determining with some degree of accuracy the extent of the tumor, the avoidance of such contaminating influence as the secretion of the nasal mucosa, the admirable cosmetic results; these and other minor considerations should, he believes, be given credit when any comparison of methods is made.

MEDICAL RECORD

November 1, 1913.

Diagnosis and Treatment of Knee Lesions in the Adult.—This paper, by V. P. Gibney, is largely made up of the reports of illustrative cases with remarks on their salient points. The diagnosis, he says, presupposes an intimate knowledge of the anatomy of the joint, deep as well as superficial. The history is of great importance, and his routine method in conducting the examination enables him to locate pretty accurately (1) the initial lameness; (2) whether pain is present when the patient is standing or walking only; (3) just where the pain is felt; (4) whether the pain persists after use and into the night. These points being established, there naturally follows a search for other factors in the etiology, such as excessive weight bearing and the strain on the muscles of the leg which would be induced by a falling arch or a poorly balanced shoe. Should no information be obtained by this investigation, a source of infection should be diligently sought out. Appropriate treatment for different conditions is described, and the author states that the lesions calling for arthroplasty are varied—loose bodies, torn semilunar cartilages, and fatty fringes do not, as a rule, respond to any-
thing short of operation. In tuberculous knees in the adult a radical treatment, such as excision, is at present about the best for men and women who are obliged to earn a living.

The Rôle of Physical Exercise in the Open Air in the Prophylaxis of Tuberculosis.—J. M. Anders states that the amount of general muscular exercise required for the maintenance of sound health by a man of average build in the prime of life is equivalent to a daily walk of six miles on a level path, while growing lads and women require somewhat less. Obviously, this daily amount of exercise is needed by those whose employment is principally sedentary. On the other hand, an active outdoor life may diminish the six miles’ walk considerably. It follows, therefore, that the details connected with the regulation of the muscular exercise will vary with the individual. He believes that well regulated physical exercise is one of the strongest safeguards we have for the maintenance of a national physique vital to the successful prevention of tuberculosis. In concluding he says he is ready to join with those who try to limit the abuses incident to competitive sports and training.

Postoperative Intestinal Stasis and the Intra-abdominal Use of Oil.—W. F. Burrows presents the following conclusions, based upon the peritoneal reaction to chemical irritation and upon the results of using neutral oil intraabdominally to control infection and effects of traumatism, both chemical and chemical, as observed in guineapigs and dogs: 1. Iodine, mercuric chloride solution, phenol, alcohol, etc., applied to the peritoneum rapidly spread beyond the area intended, through capillary action and affinity for the tissues, destroy the endothelial cells, cause an excessive exudate, and tend to produce permanent adhesions. 2. Olive oil containing fatty acids and commercial liquid petrolatum, the impurities in which are acids, resins, fats, and oils, both animal and vegetable, produce inflammation of intact peritoneal surfaces, as is shown by a watery exudate, which differs, however, from that which takes place in the absence of oil in that agglutination and organization do not follow. 3. Bland, nonirritating oil, represented by a purified liquid petrolatum obtained from Russian oil, causes none of the changes occurring in the process of adhesion formation. It has no appreciable chemical action upon the tissues or deleterious effect upon the animal, and is slowly absorbed. 4. Oil, used intraabdominally in sufficient quantity, prevents, to a great extent, the formation or recurrence of adhesions. 5. Oil fills the lymphatic channels leading from spaces denuded of peritoneum or opened by incision, thus limiting septic absorption, and, through preserving the endothelial cells, prevents extension of destructive processes. 6. Oil is used to advantage, intraabdominally, in place of salt solution, upon abdominal pads, and to protect and lubricate the abdominal contents, thereby eliminating or minimizing postoperative intestinal stasis, vomiting, and abdominal pain.

The Detection of Disturbances of the Digestive Tract by the Examination of the Feces.—C. C. Sutter finds that probably the most neglected of all our modern methods of investigation is the examination of the feces. Discrepancies have occurred between clinical observation and laboratory findings, and this has led some to consider the latter of little value in their relation to gastrointestinal disturbances. Many of these discrepancies have arisen from faulty technic, from forming conclusions from a single specimen, and from the lack of proper interpretation of the laboratory findings. Persistent and routine examinations are often necessary to detect the real gastrointestinal conditions. No laboratory findings should be taken as conclusive without the aid of an examination of the gastric contents, the urine, the blood, or the sputum; nor without the aid of a careful anamnesis and a careful and complete physical examination of the patient.

JOURNAL OF CUTANEOUS DISEASES.

September, 1913.

Intense Bronzing with Cutaneous Tumors in a Case of Malignant Lymphoma (Hodgkin’s Disease).—John T. Bowen reports a case of a young woman, thirty-six years of age; whose family history is negative, except that her mother died of tuberculosis at the age of thirty. Her personal history was also negative except that in childhood she had had trouble with her sight. She came under observation on April 29, 1912. Her trouble started two years previously, when she was troubled with itching over the trunk, which was accompanied by a few dark spots over the lumbar regions. These grew until they occupied a large part of the body, including the face and head. Where the color was more dark the skin was thicker. As time went on the itching, pigmentation, and the thickening of the skin became more marked, and they were associated with loss of weight and weakness. The thickening of the skin and subcutaneous tissue was so marked in some places and so sharply bounded, so as to suggest formation tumor. These tumor formations were seen on the right side of the neck immediately below the ear, waist, buttock, left breast, and nipple. There were no lesions of the mucous membranes. Physical examination was negative. Blood, urine, and Wassermann test were negative. On August 20th, numerous glands were found enlarged. The spleen was also enlarged. On September 10th a papular eruption developed which in type, color, and duration resembled erythema multiforme. As time went on the glandular enlargement increased, as did also the pigmentation and thickening of the skin. The tumor formation was more noticeable. On December 7th the white blood count was 18,200; on January 12th, 30,000, with an increase of lymphocytes. The patient died February 5, 1913. The autopsy revealed a malignant lymphoma of the cervical, supraclavicular, axillary, retroperitoneal, and inguinal lymph glands. Infarcts of the spleen were found, but nothing abnormal in the adrenals. The author also dwells upon the possible relationship of mycosis fungoides to leucemia.

The Leucocytes in Syphilis.—The conclusions of H. H. Hazen are as follows: 1. In normal cases the average total count of leucocytes is 7,500. The polymorphonuclear leucocytes average fifty-five
per cent., and the lymphocytes count thirty-three per cent. 2. In the untreated secondary cases there is a slight leucocytosis, an occasional case showing as high as 20,000 white blood cells. The neutrophiles are absolutely and relatively increased. The percentage of eosinophiles is higher at this time than in control cases or in cases of late lues. Treatment causes a slight drop in the total count, with a slight actual and marked relative increase in lymphocytes. 3. Under treatment a secondary case may show a lymphocytosis as high as sixty-five per cent., a condition which may persist for many months, or that may tend to approach normal in from three to five months, even though treatment is continued. 4. Cases of tertiary syphilis very rarely show an increase in leucocytes. The differential count in untreated cases is usually not far from normal. Myelocytes are rarely formed, even with moderate anemia. Treatment usually, though not invariably, causes a rise in both the relative and absolute number of lymphocytes. 5. The cases with a large papular eruption, all in this series occurring in negroes, show a higher percentage of lymphocytes than do the other types of secondary eruptions. The average is forty-two per cent. 6. In cases of secondary syphilis, negroes show a higher lymphocytosis, thirty-five per cent., than do whites, twenty-six per cent. In the late cases there is not so marked a difference. 7. Males show a slightly greater increase in the total count than do females; females show a higher lymphocyte count than do males. 8. Age makes very little difference in the blood count. The very young tend to have a high neutrophile and a relatively low lymphocyte count. 9. Marked glandular enlargement does not mean a high lymphocytosis, in fact there seems to be very little relationship between glandular involvement and the small mononuclears in the circulating blood. 10. Severe cases of secondary syphilis show a higher actual and relative neutrophile count than do the milder cases. 11. All patients of secondary syphilis that did badly under treatment, showed before treatment, a high neutrophile and a low lymphocyte count; all patients that showed a low neutrophile and a high lymphocyte did well. 12. Cases of late hereditary syphilis do not necessarily show a high lymphocyte count. 13. Eosinophilia, in a case of skin eruption, speaks against syphilis. In this series one hundred and twenty-five cases were studied, and one hundred and seventy-five counts were made. The work was done by the same person and the same technic was employed.

Salvarsan and Neosalvarsan in Syphilis: A Comparative Study.—Henry H. Whitehouse and A. Schuyler Clark draw the following conclusions: 1. Healing is as prompt and sure after neosalvarsan as after salvarsan, whether the disease is primary, secondary, or tertiary. 2. If a given lesion fails to heal under repeated injections of either, it is in all probability not syphilitic. 3. Serologically and curatively both are more effective in primary and secondary cases, than in tertiary. 4. The combined method with mercury should be used with both, in all stages of syphilis. 5. Nearly twenty per cent. more permanently negative results were obtained in all stages by salvarsan, than by neosalvarsan. 6. Five doses of neosalvarsan would seem to be required against four of salvarsan to attain the same end results. 7. Twenty per cent. of the cases under salvarsan showed reactions of some kind against eight per cent. under neosalvarsan, but twice as many are of the severe toxic type, as compared with those of the former. 8. There is less thrombosis and less inflammation of the tissues following leakage from neosalvarsan than from salvarsan.

LARYNGOSCOPE.
August, 1913.

Diagnosis of Rupture into the Lateral Ventricle and of Acute Internal Meningitis.—Ruttin mentions the fact that the most fatal way that a brain abscess can lead to meningitis is by rupturing into the ventricles, causing thereby an instantaneous flooding of all cavities and recesses of the brain and a quick spreading of the suppuration to the meninges; statistics showing that such a complication is the most frequent cause of death in those cases associated with temporal lobe abscess. The author has observed a seemingly constant symptom in these cases of acute pyocephalus internus, which is a very pronounced vertical nystagmus directed upward. Although he has observed this phenomena in several cases, his explanation is yet hypothetical; however, he believes that an irritation of the quadrigeminal region takes place.

NEW ORLEANS MEDICAL AND SURGICAL JOURNAL.
September, 1913.

Sarcoma of the Small Intestine.—E. M. Williams reports a case of this affection in which the patient, a negro eighteen years old, was operated upon on February 3, 1913, and at the time the paper was written was apparently perfectly well and had gained eighteen pounds in weight. Sarcoma of the small intestine, he states, is met with comparatively seldom, and it presents no pathognomonic symptoms. It rarely causes obstruction, and if constipation occurs it is intermittent. Diarrhea may occur, and in his case this was quite troublesome at times. It is not associated with the colicky pains present in cancer of the bowel, and as a rule the discharges are not of the dysenteric sort so frequently found in carcinoma. A symptom of very great importance is anemia, with rapidly developing cachexia. In cancer we usually have a tumor and symptoms pointing to a gradual intestinal occlusion before cachexia supervenes, while in sarcoma the reverse of this is true. It may be said that the early association of cachexia with abdominal tumor, the latter being of rapid growth, associated with fever, and without constipation, is strongly indicative of sarcoma; or, even further, that a rapidly developing cachexia with anemia, without local symptoms, and when the more common primary and secondary symptoms can be ruled out should suggest the possibility of this affection.

The Treatment of Trifacial Neuralgia by the Intragarlionic Injection of Alcohol (Hâr tel's Method).—Urban Maes states that the dangers of gasserectomy, with the frequency of relapse after the anatomical division of the sensory root, and even after the removal of the ganglion, have given way to the injection of alcohol in the treatment of
tic douloureux and other painful affections of the trigeminal. The alcohol injections into the nerve trunks at their exit from the skull is the most simple, certain, and satisfactory procedure for their relief. The final achievement in the treatment of tic douloureux is the alcoholization of the gasserian ganglion itself, a procedure which has found its ablest exponent in Härtel, of Berlin. It is not, however, without dangers, and after its employment the patient should be kept under observation for several days.

The Serodiagnosis of Pregnancy.—Chaillé Jamison and J. C. Cole, from a study based on the examination of fifty cases, express the opinion that the serodiagnosis of pregnancy is of definite value, that when proper controls of the serum and placenta are made it is as reliable as any other serodiagnostic method, such as the Wassermann or the Widal test, and that the modification suggested by Pearce and Williams (the boiling and filtration method) is simpler than the dilysis method, and just as accurate.

Treatment of Diphtheria and Diphtheria Carriers.—S. G. Wilson states that his article on this subject is based upon the treatment of some thirty cases of diphtheria as a disease and the handling of fifty carriers, among whom were transitory and permanent carriers, and the taking from the noses, throats, and in some instances ears, cultures numbering, in all, 3,000. In principle diphtheria antitoxine acts in two ways—first, by neutralization of the toxines already formed, and, second, by destruction of the false membrane, which has been shown to be the causal factor in toxine formation. The latter feature appears to be the more important, since as soon as the false membrane is checked or destroyed the patient improves. The best results in the treatment of diphtheria are obtained by large doses of concentrated antitoxine, 10,000 units, given intramuscularly, being the initial dose, with a period of twenty-four hours between doses; the membrane being the chief guide for repeating the dose, except in the laryngeal type, where the stenosis and cyanosis serve as guides. Diphtheria carriers are best treated by segregation, sunshine, and vaccine therapy. The wiping out of the disease is possible by segregating the carriers.

NEW YORK STATE JOURNAL OF MEDICINE.

September, 1913.

The Wassermann Reaction in Hereditary Syphilis, Congenital Deformities, etc. — L. Emmett Holt has studied the reaction in thirty-one cases of hereditary syphilis and in 178 children who were not regarded clinically as being syphilitic. The reaction has been tested by the Noguchi modification and in the laboratory of Noguchi himself, by one of his assistants, so that error in technic can be eliminated from the discussion. Holt comes to the following conclusions: The Wassermann reaction is almost invariably positive in hereditary syphilis, even when the patients have been treated previously by mercury, unless the treatment has been protracted and very thorough. The reaction disappears after the use of salvarsan very much more regularly and quickly than after mercury, but even so it usually requires repeated injections of salvarsan. One hundred and seventy-eight tests were made in general hospital patients who showed no definite signs of syphilis and a positive reaction was obtained in only eleven, of whom five were subsequently shown to have been fairly clearly syphilitic. A large number of patients with congenital deformities was examined and not a single positive reaction was found in a series of fifty-six consecutive cases. Only five out of a group of sixty-two patients who were suffering with marasmus or malnutrition gave positive reactions. Nearly a third of these latter had very considerable enlargement of the liver or spleen and yet gave a negative reaction. Syphilis is, therefore, not to be regarded as a common cause of marasmus.

OPHTHALMIC RECORD.

September, 1913.

The Management of Foreign Bodies in the Eye and Orbit.—Edward Stieren asserts from an experience of 180 cases of proved foreign bodies in the eye and twenty-six in the orbit, that “given by x ray the exact location of a magnetic foreign body in the vitreous, we subject the eye to much less traumatism if we insert the cone shaped tip of the magnet in a sceleral wound made with a sharp cata- racet knife at a point as nearly opposite the foreign body as possible than to have the foreign body force its way through lens or ligament, iris, or ciliary body.” He reports a case in which he removed a piece of steel from the vitreous with the recovery of normal vision. He is accustomed to supplement the surgical procedure with measures intended to promote absorption of retinal and vitreous hemorhages and exudates, such as diaphoresis in the electric cabinet bath, salicylates and mercury, the latter in the form of gray oil hypodermically. Dionin and hot stipes to the eye are never omitted. Recently he has been using the galvanic current in vitreous opacities, and he thinks it has a beneficial effect in promoting their absorption. Foreign bodies in the orbit are well borne, unless they consist of brass or copper, but glass and wood will not remain quiet, wood having a tendency to create fistulous tracts, and glass to wander. The search for a foreign body in the orbit is difficult, even though it has been accurately localized, and much damage is apt to be done, so, unless there is an urgent demand for its removal, it is better to allow it to remain. When removal is necessary it should be done through a free incision in the skin, so as to get as good a field as possible in which to work.

Cacodylate of Sodium in a Case of Keratoiritis Due to Lime Burn.—Frank Allport and Alexander Rochester report a case of lime burn of the eye in which an intramuscular injection of seven grains of sodium cacodylate was given one week after the accident, followed by injections of half that dose at intervals of a few days. During this time the usual treatment for lime burn was maintained. The cornea began to clear gradually two or three days after the first injection, and continued to do so slowly and steadily until it became absolutely transparent. With his refractive error corrected his vision was 20/20. It is to be remembered that opacities due to lime burns are not simply scars, but contain deposits of calcium carbonate. Possibly, therefore, the sodium cacodylate, finding its way from the blood into the lymph channels
and finally into the cornea, brings about some chemical reaction with the deposits of calcium carbonate rendering them more soluble and more readily removed.

The Effects of the Ingestion of Various Oils upon the Leucocytic Picture in Pulmonary Tuberculosis.—Myer Solis-Cohen and Albert Strickler have employed the Arnth method of leucocyte enumeration in this study because they believe that the findings afford a fairly definite basis for determining whether or not a given therapeutic agent is benefitting a patient. They have found, in a long series of observations, that improvement in a tuberculous patient is usually associated with certain fairly definite changes in the leucocytic picture. These changes are an increase in the proportion of lymphocytes, and, less constantly, an increase in the proportion of polymorphonuclear leucocytes having one and two nuclei. The method has the great advantage of ruling out the uncertain element of the personal equation in the estimation of results, particularly as the one making the cell counts knew nothing of the treatment or progress of the patient from whom his specimen was obtained in any case. Thirteen patients were given oils of one or another variety and in eleven of these the first two classes of cells of the Arnth count were diminished; in the other two they were increased. The lymphocytes were increased in seven and decreased in six. All the patients receiving olive oil showed a diminution in the percentages of lymphocytes and of the polymonuclear cells having one and two nuclei. In all the patients taking cod-liver oil and cotton seed oil there was a decrease in the numbers of the first two Arnth classes of cells, and an increase in the percentage of the lymphocytes in all but one. Those on petroleum and those taking an emulsion of beef fat, butter fat, olive oil, lard, and peanut oil with proteins showed inconstant results. The authors remark that it is impossible to draw conclusions from thirteen cases, but that it would seem as though the ingestion of oils in itself has no decided effect on the blood picture so far as the proportion of lymphocytes is concerned, and hence upon the resistive power of the patient, for the proportion of lymphocytes may be taken as an index of this power. Oils, however, do seem to reduce the proportion of polymonuclear cells of the first two classes of Arnth. This is regarded as a sign of improvement by most observers, but previous work by the authors does not incline them to this view. “It is suggestive that all the patients taking cod-liver oil and cotton seed oil showed an increase in the proportion of lymphocytes, with one exception, and a decrease in the first two classes of Arnth.”

A Case of General Sepsis following Peritonsillar Abscess.—H. H. Martin reports this case, that of a young, healthy married woman with negative history, in which an indolent peritonsillar abscess was followed by a simultaneous infection of the right lung and of the pericardium, and later by two metastatic infections of the same indolent character as the first abscess. He gives the following summary: Peritonsillar abscess can occur without preexistent or coexistent tonsillitis, and may be a local manifestation of a very serious general infection. Such infection may follow a peritonsillar abscess, either by direct infection of the bronchial mucous membrane through the larynx or trachea or indirectly by metastasis. The fact that a pathogenic organism cannot be demonstrated in the blood stream is of negative value in the diagnosis of general sepsis. An autogenous vaccine is of unquestionable value in a case of this kind. The question uppermost in the mind of the author is, was the peritonsillar abscess the first cause in this case, or was it simply the first local manifestation of a pre-existent general infection?

Etiology, Prophylaxis, and General Management of Enterocolic Infections in Infants.—E. P. deBellard states that two facts stand forth prominently in the light of our present knowledge. First, that there is no specific pathognomonic organism accountable for all cases of enterocolic infection; and, secondly, that the bacteria constituting the usual normal intestinal flora of babies are only infrequently the direct cause of the disease. He gives the following summary: 1. Intestinal toxicoses prevail epidemically in large cities every summer and are due to some predisposing factor plus infection. 2. The starting point of the disease can usually be traced to some previous metabolic or alimentary disturbance. 3. An average temperature of over 60° F. seems to be a prerequisite for the inception of an epidemic. 4. The conditions favoring the development of these diseases are readily created artificially, even in the winter time, by overheating, overclothing, and improper ventilation. 5. They are largely preventable by educating the public in health matters, and as the medical profession constitutes the legitimate channel through which this knowledge must be disseminated, we should all join in one great effort to accomplish the task and save the lives of thousands of infants who needlessly die every year.

A Successful Method of Performing Shockless Operations Based on a Clinical Experience of Three Thousand Cases.—The anoci association method of Crile has already been described in the Journal (pp. 297 and 345). In the present paper, by that author, he summarizes as follows: The brain, being a tissue of surpassing delicacy, is damaged with wonderful facility by injury and by fear and worry. The good risk patient when operated upon by almost any method, by almost any surgeon of experience, will recover from his operation; but the delicate nervous organization is only too frequently shattered by the experience. We now understand why. Though the principle is clear, the technic demands to a certain extent the reeducation of the surgeon; it demands a certain amount of detail and precision; it demands far more consideration for the patient. But through anoci association the destiny of a patient is to a greater degree placed under the control of the surgeon, who through it is enabled to reduce both the morbidity and the mortality.

**Treatment of Cutaneous Epitheliomata.**—According to J. N. Edmondson, the first item for consideration in attacking this form of carcinoma is to
note its pathological character, whether of the tubular or lobular type, as in the latter the tendency of the growth is downward and into the connective tissue, and therefore a more penetrating technique is indicated. The methods at present adopted for combating these new growths are, excision, curettage, caustics and caustic pastes, actual cautery, fulguration, carbon dioxide snow, radium, and Röntgen ray. Where it is necessary to remove the adjacent lymphatic glands he advocates the knife, but insists that an area very much larger than the lesion be incised, and a clean dissectin be made of the surrounding lymphatics. In general, he regards the x ray the proper treatment for the following reasons: 1. Its freedom from pain; 2. its lack of scarring; 3. its thoroughness in covering the field surrounding the growth, as well as the attack on the growth proper; and, 4. by far the most important, the results obtained as compared to any other method.

Proceedings of Societies.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, October 20, 1913.

The President, Dr. REYNOLD WEBB WILCOX, in the Chair.

Tuberculosis Patients Treated by a Special Method and Control of Cure.—Dr. C. AM ENDE said that the medicines prescribed by him were gelatin coated pills containing one grain of quinine sulphate, with one fifth of a gram of iodoform, and cresote, preferably in five drop doses, in capsules. For convenience, the cresote might be given in pill form, though pills containing more than three grains did not keep well. The dispensing of these remedies by the physician himself assured the advantage of control over patients, many of whom would not otherwise take them regularly. In making the early diagnosis of tuberculosis Doctor Am Ende employed, in preference to tuberculin injections, the Moro salve, containing equal parts of tuberculin and hydrous wool fat, which, when rubbed in at the pit of the stomach, produced within two days a characteristic efflorescence. Although the cases were comparatively few as yet, he stated, evidence as to the efficacy of his method was accumulating, and the improvement of patients under its use might perhaps establish it as a specific for tuberculosis. In the absence of complications the treatment was simple and free from danger. Originally it was based upon the principle of internal antisepsis, but this idea had to be changed for the active agent in the production of the Moro reaction was tuberculin, a substance most probably elaborated by the body cells upon stimulation by a toxic material in the bodies of dead tubercle bacilli,—which substance was inimical to and destructive to the bacilli when living. The basic element, then, in this process was the dead bacilli; without these, immunizing tuberculin did not develop. With the chemicals mentioned, however, the process must differ. In the usually slowly advancing disease effective bacilli were ab-

sent; therefore their presence could have been brought about only by the chemicals which served to kill them. After that the two processes might well go on hand in hand, so to speak; immunization predominating over the killing, and vice versa. If this reasoning were correct, it might explain his unusual results. In conclusion, he said that if people in general could be made to comprehend that a person might have pulmonary tuberculosis entirely unknown to or unascertainable by himself or his friends, and thus be induced to consult their physicians concerning anything unusual in their state of health, considerable reduction in the mortality from this disease might result, to say nothing of the misery and expense which would thus be spared. In connection with these remarks he referred to several of his cases and presented three of the patients before the association. In addition to the pills and cresote, one patient, an adult male, was at present receiving injections of tuberculous vaccine. This had previously failed both in England and Germany when used by itself, but it was possible that in combination with the internal medication it might prove beneficial.

The Theory and Treatment of Diabetes.—This paper, by Dr. WILLIAM EDWARD FITCH, will be published in the Journal.

Diabète Azoturique of the French.—Dr. ANTHONY BASSLER read this paper. The classification of azoturia which he makes, into physiological azoturia, azoturia simplex, and azoturia gravis, was briefly referred to in an editorial in the Journal for November. In physiological azoturia Doctor Bassler said that for some reason an increased oxidation took place in the body and an increased output of nitrogen bearing substances in the urine was liable to occur. The causes included cold, excess of exercise, sometimes the emotions, physical pain, repeated pregnancies, prolonged digestion of protein foods, and the like. The term might also be applied to abnormal states of the body such as continued fever and some of the acute lesions and functional disturbances of the nervous system, but these were only relative. The characteristics of azoturia simplex were the absence of the constitutional symptoms, its more acute or limited course, the fact that polyuria was absent or of slight degree, and the output of urea and the phosphates only moderately above normal. It was met with in both children and adults, mostly the latter. Emotions, traumatism, suffering from painful affections, and excessive indulgence in food and alcohol might be factors in its production. A case of this simple form might continue for a considerable length of time, finally deepening into the grave type. In the majority of instances, however, if the condition was recognized and was properly treated, it subsided after some weeks. What might be considered a case of azoturia simplex should make one hesitant in the prognosis, for while the diagnosis of such a degree of the condition could be based only on the severity of the symptoms and the course under treatment, a progression might nevertheless take place. Azoturia gravis was the most important form. It was met with mostly in male adults between the ages of forty and forty-five and those suffering from lesions of the brain and spinal cord, syphilis, painful affec-
tions, the long continued use of alcohol, and overindulgence in nitrogenous foods. It was debatable whether the condition was brought about by a disturbance of the nervous system, as suggested by Bouchard, or a metabolic disturbance of the general organism. Argument was presented by the reader of the paper to show that the symptoms were due to constitutional causes, and that the nervous disturbance was consequential. He was of the opinion that the condition was of hepatic origin, and that the pancreas also played an important part, for we knew that the pancreas had to do with the transformation of the nitrogen bodies, as well as the carbohydrates. The symptoms were, progressive emaciation, exaggerated appetite and thirst, various neuralgias, disturbances of the special senses, abundant sweating, loss of muscular strength, hemorrhage of the retina and vitreous, and cachetic edema. An increased craving for food might alternate with complete anorexia, and as the case progressed anorexia might alternate with polyphagia. There was usually pain in one of the loins and legs; and boils, smaller than those met with in diabetes mellitus, might occur. The principal symptom upon which the diagnosis of this and the other forms was made was the azoturia, which required the examination of a twenty-four hour specimen of urine. The amount of urine excreted was usually about five litres, though sometimes running as high as twenty. It might be light or dark in color, was of a very pronounced acidity, and the specific gravity often exceeded 1.040, or even 1.050. There might, however, be a low specific gravity; in which case the symptoms were generally connected with the central nervous system, and were only mildly constitutional. The urine quickly became ammoniacal upon standing, because of the amount of nitrogen bearing substances being broken down by bacteria. There was no albuminuria or glucose in it, though an albuminuria might be noticed in the beginning. Its main feature was the azoturia present; by which was meant an excess of urea, uric acid, and nitrogenous extractive substances. In the course of twenty-four hours the urine output was between forty and 150 grammes (normal amount twenty-five grammes, although lately this had been considered too high, and sixteen grammes was now regarded as normal). The uric acid reached nine grammes (normal amount 0.7 grammes), and the nitrogenous extractives of creatinin and urocanthin reached and exceeded seventy grammes. The excess also involved the chlorides and phosphates, the former of which might be between fifteen and thirty grammes (normal about thirteen grammes), and the latter, represented in phosphoric acid, from five to six grammes (normal about three grammes). In the absence of facilities for making the nitrogen partition, urea might be taken as the diagnostic index of the condition. The accurate methods of analysis of Mörner-Sjögqvist and of Folin were, of course, advisable, but when these were not practicable the ordinary urinometer (multiplying the quantity of nitrogen obtained from one c.c. of urine by the number of cubic centimetres voided) was sufficient for clinical purposes. The presence of a moderately increased amount of urea suggested the simple form, while the presence of a large amount, with the characteristic general symptoms, indicated the grave form. The Ehrlich aldehyde reaction, which was uniformly positive in azoturia, should also be noted. It was advisable that urea estimations should be made in all cases of diabetes mellitus, phosphatic diabetes, and even diabetes insipidus, for the particular case under observation might be a mixed one, and when present with glucose azoturia was much more serious.

Doctor Bassler went on to say that while diabetes mellitus was common, phosphatic diabetes (or, better, phosphaturia) was less common, and azoturic diabetes (or, better, azoturia in the forms he had classified) the rarest of all. It was important to keep in mind that azoturia might coexist with diabetes mellitus; in which case the prognosis was much worse than it would be in either affection alone. The treatment suggested that more estimations of urea should be made in a general routine way, for by this means all cases of the simpler forms would be recognized sufficiently early and successfully treated. The condition once established, the treatment consisted in a judicious management to prevent further mischief. Relinquishment of work was essential, and a sojourn in the country might be sufficient for the simpler forms without other treatment. The patient should rise late and go to bed early, so as to spare the nervous system, and the avoidance of movements and fatigue should be advised in order to limit the loss of urea. The bowels should be kept well open, and a tepid sea water bath or shower, followed by a good towelling, had been recommended by Ralfe. While care should be taken that the temperature should not be too low, it was important not to let the patient become relaxed from too hot rooms or too heavy clothing. While on the one hand it seemed advisable to restrict the amount of nitrogen in the food, on the other, this had not proved as serviceable as placing the patient on a general diet. The main point in the dietetic treatment was not so much to control the nitrogenous element as to regulate all quantities of food, so that the tissues should not be oversupplied, and the patient still be sufficiently nourished. This plan controlled the general symptoms, as well as the urinary ones; but fell somewhat short as regards repair of loss of tissue. If the patient recovered sufficiently, however, one was warranted in increasing the amount of nitrogen, as well as of carbohydrate and fats, which meant more food. There was some difference of opinion as to the value of different drugs, although most authorities agreed that valerian answered the best purpose. Bouchard employed it with good results in the form of the extract, in gradually increasing doses: beginning with eight grammes in fractional doses during the day, and later bringing the amount up to twenty or thirty grammes in the twenty-four hours. Others recommended arsenic, potassium bromide, belladonna, and hyoscyamus, but it was probable that the best drugs were valerian, opium, and arsenic. The prognosis in the different forms mentioned varied according to the degree and duration of the affection and the presence of complications. When properly treated all cases of the simple form were cured, while in the grave form the symptoms of most were relieved.
and the patients enabled to live for a number of years. In the presence of complications, however, but little could be expected. This meant an extreme degree of breaking down of tissues, and usually marked the beginning of the end.

Infantile and Juvenile Diabetes.—Dr. Louis Fischer read this paper, the principal points of which were as follows: Research had not yet enlightened the dark chapter of the etiology, for the origin and causation of infantile diabetes was still obscure. One teacher believed that the absence of the pancreatic ferment during an attack of pancreatitis caused diabetes. We knew that a disturbance of fat or carbohydrate metabolism was responsible for the glycosuria. That the internal secretions played an important rôle in influencing the metabolism of fat and casein and also the carbohydrates was recognized to-day. As the physiology of the adrenal system, with the thymoids and parathyroids, became better understood we would know more of the relationship which the internal secretion of the pancreas bears to the proper metabolism of sugar in the human economy. Diabetes was by no means rare in children. It occurred far more frequently than was commonly supposed, but the condition escaped detection because of the difficulty in procuring specimens of urine from infants. Pavly had reported 1,365 cases, among which eight were under ten years. Reden reported 1,003 cases; fifty were under ten years. 47 between ten and fifteen years. Saundby reported 2,011 cases, with fifteen below five years, fifty-eight below ten years. Hagenbecker reported a series of seventy-seven cases, all of them under one year. Over-taxing the system with an excess of sugar, such as candy or honey, had frequently been recorded as an etiological factor in the causation of infantile diabetes. Acidosis was generally considered to be a result of the diabetic condition. It was very probable, however, that an acid condition might have much to do with the causation of diabetes. This condition had been termed acidemia—excessive acidity or, rather, decreased alkalinity of the blood. It had no connection with the term acidosis, this latter being considered as occurring only when oxobutyric acid or its congeners (acetone or diacetic acid) are present. Acidemia was an extremely common, every day occurrence and, unfortunately, it was all too often overlooked in routine work. A one sided dietary in which meats, fish, fats, etc., predominated produced organic acids, whereas a dietary of cereals, milk, vegetables, and fruits tended to maintain the normal alkaline condition, by reason of the food salts they contained in their best and most assimilable form. According to the theory of Naunyn and his school the diminution of the alkalinity of the blood and tissues was at the root of the essential nature of the diabetic intoxication. Glucose was not only found in the urine, but also in the blood. In addition to the excretion of sugar, there might be oxobutyric and diacetic acids; frequently also acetone and beta-oxobutyric acid. The examination of the blood in juvenile diabetes showed frequently a lipemia. At Professor Ortner's clinic Dr. Erich Stoeck found this fatty condition of the blood in many cases of diabetes and called attention to the fact that the fundus of the eye would show such a fatty condition of the blood when present. Klemperer and Umber found that the lipemia of diabetes was a lipidemia.

To treat diabetes intelligently each and every case must be studied individually. The food tolerated by one might prove disastrous to another. The aim in treatment should be to procure a tolerance for the carbohydrates, notably sugars and starches. One should try fresh air, milk, oatmeal, potato, fresh fruits, and honey. Fresh fruits and honey both contained levulose; they would be well borne at times, and would not increase the sugar excretion, whereas they were contraindicated in many other cases and might do harm. Tomato, spinach, and watercress, soups, eggs, chicken, boiled beef, asparagus, cabbagae, lettuce, and almonds should form the bulk of the diet. One of the prime factors was rest in bed. Avoid exercise and excitement as the nerves played an important part in the etiology. Atropine methylbromide, 1/120 grain three times a day for a child five years old, or sulphate of atropine, from 1/200 to 1/100 grain three times a day. When there was marked acidosis bicarbonate of soda, from ten to fifteen grains, might be given several times a day. Vasomotor efficiency must be maintained by systematic hydrotherapy; thus the cold water spray or shower in conjunction with massage might aid in stimulating the circulation and indirectly aid in the proper metabolism of the carbohydrates.

In the discussion Dr. Edward E. Cornwall said that in the literature on the treatment of diabetes one point appeared to have been overlooked which he believed to be of vital importance, and that was that the diet should be so arranged as to make as easy as possible the processes involved in protein metabolism; that in the treatment of this affection insufficiency of protein metabolism, as well as insufficiency of storage and combustion of carbohydrates, should be considered. The dietetic treatments for diabetes which were in vogue looked only to the restriction and selection of carbohydrates. They failed to regard nitrogenous metabolism, and, worse than that, they imposed unnecessary burdens upon it, both by giving protein in excess and also by giving it chiefly in a form the metabolism of which was comparatively difficult namely, animal tissues; for protein in that form put upon the liver, already incapable of properly performing its carbohydrate metabolic duties, the work of breaking up putrin bodies directly introduced with it and products of its putrefaction by the saprophytic bacteria in the intestines. The instability of the liver in diabetes as regards its glycogenic function we would naturally expect to be increased by such treatment, and it might be that this was partly responsible for the extreme limitation of carbohydrates which had so often been found necessary in order to clear the urine of sugar. The reasonableness of the argument presented received emphasis from consideration of the fact that a large proportion of cases of diabetes were found in families in which gout, chronic arthritis, chronic nephritis, apoplexy, and cardiovascular disease were prevalent. It was in treating persistent glycosuria in such patients, whose nitrogenous metabolism was obviously deficient.
that his attention had been drawn to the therapeutic value of an “easy” nitrogenous diet in diabetes. The therapeutic principle to which he referred was not limited to diabetes. It had a wider application, and might be formulated thus: In any condition in which the body was laboring under one particular burden of disease, relief of other burdens, physiological or pathological, enabled it better to bear and to throw off the particular burden. In the case of diabetes, making easier the burden of nitrogenous metabolism facilitated the rectification of carbohydrate metabolism.

Dr. Robert L. Watkins said he had been pleased to note Doctor Fischer’s mention of the fact that diabetes was in some cases associated with syphilis. In cases of azoturia he thought it would be well to look for crystals of uric acid in the blood stream. He had observed not only uric acid crystals, but also those of the triple phosphates, and in some instances cystine, in the six sided crystals. He called attention to this because many had an idea that such bodies were not visible. By carefully drawing the blood and examining quickly, before the drop dried too much, his experience was that they could frequently be seen. Cystine was always insoluble, on account, he supposed, of the contained sulphur element.

Dr. J. Wallace Beveridge said that in the papers this evening one important fact in connection with diabetes had not been touched upon, and it seemed advisable to indicate what, to his mind, offered one of the principal obstacles met with in the treatment, as well as one of the fundamental causes. In the observation of many cases of diabetes during the past few years the gastric contents had been examined by him, and in over eighty per cent. extensive acidity of varying degree had constantly been found present. Furthermore, the radiographic analysis of the stomach by Dr. A. J. Quimby showed, in over seventy-five per cent. of the cases, dilatation with mechanical defects in the intestines. It had been proved by Bayliss and Starling that a hormone, named secretin, was manufactured in the epithelial cells lining the pylorus and duodenum as the result of acid stimulation. In normal digestion we had a sufficient amount of secretin evolved to activate the normal internal pancreatic secretions to complete digestion without any interference with metabolism, and secretin was now unquestionably given the principle rôle as the activating agent of the pancreas. Consequently, when we had an increased acidity of the gastric contents an overproduction of secretin necessarily ensued, and this overstimulated the pancreas to an increased production of the internal secretions which in time, if permitted to continue, would cause a degenerative change in the pancreas and not only interfere with the breaking down of the carbohydrate group, but also cause inability to attack the protein molecule. Again, other factors would be lesions such as ulcers, stenosis, or any change in the pylorus or duodenum which might interfere with the normal production of secretin. The intestine played an important part in the digestion of the diabetic, but time would not permit of his entering into a discussion of this function, except to say that intestinal putrefaction should in all cases be carefully guarded against.

Dr. Charles Herrman thought that diabetes was comparatively rare in childhood, and especially in infancy. The same case was often seen by several observers at different times, and hence the cases of the disease appeared more numerous than they actually were. It was only in small infants that there was any difficulty in getting a specimen of urine for examination. After a child was two years old there was no such difficulty. While it had been remarked that diabetes was unusually common among adults of the Hebrew race, this did not appear to be the case in children. He was connected with three large institutions in which the clientele was principally Jewish, and in fifteen years he had met with only two instances of diabetes among the children. It seemed probable to him that syphilis was a more important factor in the etiology of the disease than had been supposed. The specific affection was no doubt often latent, but now that we had the Wassermann reaction to aid us the detection of its presence presented less difficulty. Doctor Fischer had spoken of the association of diabetes with pertussis. It was a fact, however, that sometimes in pertussis the urine reacted to Fehling’s test without true diabetes being present. It was also necessary to differentiate alimentary glycosuria from true diabetes, for while the one was of little significance and easily cured, the other was extremely serious, since it was well known that the prognosis in this disease was worse in children than in adults. It was true that we did not meet with the same complications as in adults, but there was not sufficient time for these to develop. The disease was apt to run a comparatively rapid course and terminate in coma. He had tried the use of atropine, as recommended by Rudisch, but while it might control the glycosuria, it did not seem to have any effect upon the progress of the actual disease. He thought it advisable that children suffering from diabetes should be cared for in a hospital or sanatorium, where they might be under constant supervision and the dietetic treatment could be carried out more systematically.

Dr. Robert T. Morris said that Doctor Beveridge was the only one who had approached the surgeon’s point of view in relation to diabetes. Every one of these patients should be sent to a gastroenterologist in order to obtain a report upon the question of intestinal putrefaction. Toxins which were byproducts of intestinal bacteria excited secretion of morbid secretin. Hormons which dictated function to the pancreas gave wrong messages. In addition to that, the pancreas in cases of intestinal putrefaction was frequently in a state of chronic congestion.—Interstitial pancreatitis occurred very frequently and was unobserved by the clinician. In certain cases in which the islands of Langerhans were squeezed they ceased to function properly, and diabetes mellitus was a common symptom. Diabetes mellitus was never a diagnostic entity; it was always a symptom. There were several causes for this symptom. We might have irritation of the floor of the fourth ventricle of the brain from toxic, mechanical, or reflex causes, and in these cases diabetes mellitus was a symptom.
Letters to the Editor.

WHITEHALL BUILDING,
NEW YORK, November 5, 1913.

To the Editor:

In a review of the second edition of Doctor Chapin's Sources and Modes of Infection, which appeared in a recent number of the American Journal of Public Health, the following quotation is taken from a new paragraph on School Disinfection in the work in question: "All evidence points strongly to the fact that when children contract infectious diseases in school, the channel of infection is not by means of school desk or floor but by the personal infection of another child." I shall be glad if you will allow me to call attention to the fallacy underlying this well known ipse dixit of Doctor Chapin. As I have pointed out elsewhere, there is absolutely no evidence that infection is not transmitted through the agency of fomites. On the contrary, if proof be needed of what is generally regarded as axiomatic, a few simple experiments would be sufficient to show that infection can be readily transmitted in this manner. We are probably all agreed that direct infection is more common than infection through the agency of fomites, but there are certainly no grounds for the contention that the latter may be safely ignored.

Doctor Chapin is further quoted to the effect that "recent bacteriological studies of schoolroom air in New York have shown that ordinary quiet air must be a wholly insignificant factor in the spread of disease." This is undoubtedly true; but why "quiet air"? The only time in which the air of the schoolroom is quiet is when the children are not in it, and when, consequently, it is a matter of no importance whether the air be quiet or not. During school hours the air is not quiet, and moreover, the movements of the children keep the dust in constant circulation. In this connection, it is interesting to recall the fact that the reviewer himself has recorded the presence of 24,700 acid-forming streptococci in a single gramme of schoolroom dust taken from an average of nineteen samples.

Doctor Chapin's whole attitude in regard to disinfection is as incomprehensible as his attitude toward fly bourgeois for I venture to suggest that his "scepticism" in this matter, to which the reviewer refers, is shared by few other medical men of equal standing.

J. T. Appia Walker.

KYMOGRAPH AND KYMATOGRAPH.

173 Lexington Avenue,
New York, November 3, 1913.

To the Editor:

I shall thank you for coming to my aid by publishing my objection to the word Kymograph when Kymatograph is meant.

In all American and all German medical lexicons, in American and German medical literature by the term Kymograph is understood an instrument recording wave-like motions; in reality, however, it is the Greek name for measure of the length of segments of line, and the correct name for that instrument is Kymatograph (Kyma, Kymatos). Noticing such error, which the small boy in Greece would recognize, I cannot help correcting it, but this is sometimes not apparent. Pathologists will dispute, quoting what they erroneously think are authorities.

The worst errors in our nomenclature are among the new formations made, by those who know only our school Greek, by means of the lexicon. We may call this lexicon Greek, and when we think of the everyday nonsense produced by foreigners who wish to express themselves in English by means of the dictionary, Gott schanze Dich! The lexicon gives: schuchen, to guard, to protect, to shelter, to damn. And he selected the shortest of the words for the name.)

A. Rose, M.D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Although so large a subject as bacteriology cannot be adequately treated in so small a volume yet this quiz compendium contains the more important points. It does not go into any detailed discussion but it admirably fills the purpose that its author had in view, "To serve the needs of the medical student preparing for examination, and for the practitioner of medicine who desires to acquaint himself with the principal facts of the rapidly growing science of bacteriology." The illustrations are well selected and the plates showing the various forms of malarial organisms are excellent.

Genitourinary Diagnosis and Therapy. For Urologists and General Practitioners. By Dr. Ernst Portner, surgeon in Urology in Leipzig. Translated and Edited by Bransford Lewis, M. D., B. Sc., Professor of Genitourinary Surgery, Medical Department of St. Louis University. Genitourinary Surgeon to St. John's Hospital, etc. With Forty-three Illustrations. St. Louis: C. V. Mosby Company, 1913. Price, 221. (Price, $2.50.)

This book is full of unexpected thrills: Thus, on page 14, we read, "While arsial, as with all other drugs used for this purpose, is occasionally attended with indifferent success;" on page 15, "Erections and emissions must receive attention as they may be suppressed;" and on page 125, "The usual surgical treatment of renal calculus is nephrectomy with very good result." These are but a few among many Anglo-German efforts. While they lend a welcome flavor of the German nation, and, we think, do not help its reputation. The chapter on acute gonorrhea is thoroughly German. For instance, under "dietetic instructions," "Alcoholics are to be avoided excepting small quantities of red wine and light beer. Alkaline spring water as well as lemonade and other acid drinks are to be avoided as they make the urine alkaline and thereby tend to induce mixed infection." On page 18, the author speaks of posterior urethritis as one of the complications of gonorrhea. But he is not set right by the editor who gently suggests that the term complication is hardly justifiable as it occurs in eighty-five per cent, to ninety-five per cent. of cases. The author's treatment of gonorrhoea is a peculiar mixture of the older and the more modern treatment by means of silver salts. For instance, he uses allargin in the abortive treatment, but if there is no question of abortion he starts the pa-
tient on home injection of thallium sulphate or, 'if this is too expensive,' potassium permanganate. In four or five days if the patient is getting better silver nitrate is alternated with these injections. In describing the treatment of the posterior urethra he does not at all mention the very common method of inserting a catheter into the bladder, directing the catheter into the sigmoid, and, after withdrawal of the catheter, allowing the patient to urinate. There is a growing tendency in books of this sort to suggest but one make of instrument; Page 57, 'If the catheter has been pushed back into the bladder this is readily corrected by the means of the editor's operative cystoscope.' We know several operative cystoscopes which might successfully be used for a similar purpose; indeed we read on the previous page, "By means of the editor's operative cystoscope the bladder has been removed." Throughout the book there are countless prescriptions, many of them with, to the reviewers, unknown drugs. We note that he considers methylene blue a urinary antiseptic and an anti-neuralgic; also on page 122, renal tuberculosis, "Very slowly developing, practically stationary cases get well." This aside from being interesting English is a statement founded upon no pathological data. Under diseases of the kidney the author has a portion devoted to the treatment of various methods of preserving the kidney, although it is generally neglected in most English genitourinary works. Throughout the book the author mentions practically every disease ever heard of, but is unduly biased toward each disease in turn. In connection with a cystocele all that he says of diagnosis is: "A cystocele is a saccular prolapse of the floor of the bladder toward the vagina. It usually follows upon prolapse of the vagina." There is an excellent appendix by Dr. Rudolf Schwalb. This numerals the difficulties and specific treatment of gonococcal infection. It is interesting how long it takes one country to get ideas and methods from another. We have reviewed at least three modern English books on urology during the past year and in not one of them has the medical opinion on gonorrhea been mentioned—here is another foreign book in which this important subject is covered by an American. In short we feel that much time has been wasted upon this work which the editor and contributors have spent in giving us a really good book by its own hand.

A Course in Normal Histology. A Guide for Practical Instruction in Histology and Microscopical Anatomy. By Rudolph Krause, a. o. Professor of Anatomy at the University of Berlin. Translation from the German by PHILLIP J. R. SMHALL, M.D., New York. With Three hundred and 208 Colored Figures. Arranged on Ninety-eight Plates after the Original Drawings by the Author. New York: Rebman Company, 1913. Part I. Pp. x-86. Part II. Pp. x-406. Professor Krause is a firm believer in the serious advantage accruing to the physician who is well trained in normal histology, the handmaiden and precursor of morbid histology. He advocates the utilization of an entire summer semester for the study of the subject—a view which any one familiar with the wonderful help that histology affords the understanding of tissue structure and the departures therefrom incident upon disease cannot but sustain. The work before us has for its object to supply a practical education in this branch of medical knowledge. It is composed of two volumes, one of which binds both of these books, contains, very clearly though succinctly enunciated, the technical of the whole subject, including the use of the microscope and the microtechnique—that is to say, all those methods which serve to produce accurates the methods of observation, and the methods of injection—the filling of any hollow structure with stained or unstained materials—menuration and drawing of microscopic preparations are also given in detail. The book is a collection of more than five hundred and eighty superb histological plates of tissue and organs with their brilliant stains, all presented with a care and degree of perfection seldom equalled in works available to the student. Each plate is accompanied by instruction in the process of histological preparation and a description of the illustrations. The translator's part in the work has been admirably done and the publishers are greatly to be praised for the care shown in the production of the work, which is bound to set a favorable reception in this country.

Orthopedics in Medical Practice. By Professor ADOLF LORENZ, Director of the Imperial University Ambulatorium for Orthopedic Surgery in Vienna, and Dr. ALFRED SAX, Assistant Surgeon in the Imperial University Ambulatorium for Orthopedic Surgery in Vienna. Authorized Translation from the German by L. C. PEEL RITCHIE, Ch. M., M. D., F. R. C. S. Edin., Late Voluntar-Arzt in the Imperial University Ambulatorium for Orthopedic Surgery in Vienna, etc. With Thirty-nine Illustrations by William Wood & Co., 1915. Pp. xvi-388. (Price, $3.)

This translation of Adolf Lorenz and Alfred Sax's work affords English readers a valuable illustration of the importance of having at least a superficial knowledge of orthopedics when the general medical practitioner is called upon to consider internal medicine. The effect of the writers is to reach back to the beginning of those conditions that ultimately become classified as orthopedic. In the early history of such conditions there is almost invariably a more or less prolonged period when the symptoms were sufficiently pronounced and yet failed to impress the internist with their true character. Thus the reflex pains of tuberculous diseases are generally considered symptomatically. Valuable time is lost and ultimate results for carelessness in the late stages. The chapters are devoted respectively to Diseases of the Respiratory, the Circulatory, the Digestive, the Urinary, the Nervous, and the Locomotory Systems. The comprehensive preface by Adolf Lorenz explains the purpose and contents of the book, and the pages that follow are replete with valuable information from the extensive clinical experiences of the authors. The brochure should be read by every one who attempts to minister to the ailments of either children or adults, for the internist or internist will welcome such a storehouse of information bearing upon his attitude as diagnostician. Throughout the book there are clearly described methods of applying orthopedic principles by the medical diagnostician in the avoidance of complications of the disease and protracted delay in appropriately obtaining the cooperation of the orthopedic surgeon where such is demanded. The references to German literature are very complete, and, while only critical, is the compilation following the bibliographical references equally important in literature in other languages.

Modern Ophthalmology. A Practical Treatise on the Anatomy, Physiology, and Diseases of the Eye. By JAMES MOORES BALL, M. D., LL. D., Dean and Professor of Ophthalmology, American Medical College of St. Louis (Medical Department of the National University of Arts and Sciences). Third Edition. Revised and Enlarged. With 445 Illustrations in the Text and Numerous Figures on Twenty-four Colored Plates. Philadelphia: F. A. Davis Company, 1913. Pp. xxiv-991. (Price, $7.50.) This admirable textbook needs no introduction, but how it has grown with the advancement of ophthalmology several chapters have been rewritten, and some new ones have been added, together with much new material that brings the book well up to date. If we wished to be captious we might point out the omission of such operations as Tott's dacryorhinostomy, of Homer Smith's ripening operation for cataract, and the fact that we have been unable to find any mention of the asthenopia caused by intranasal conditions; but omissions will occur in every book and this one is the more welcome for it is the author, who has given us one of the best textbooks for the student, and of the most useful reference books for the practitioner now on the market.

Coprostasis. Its Causes, Prevention, and Treatment. By SIR JAMES SAWYER, of London, Doctor of Medicine of University, Fellow of Royal College of Physicians, Lumehan Lecturer, etc. Birmingham: Cornish Brothers, 1912. Pp. 74. This little book of seventy-four pages is well worthy a few review, so chatty is it written, so wise and practical the descriptions and recommendations. Not only are the salient points of 'this perennial and daily topic of a physician's practice' succinctly and clearly covered, but certain of large importance (in the opinion of the reviewer) are also described; such as the significance of
Medical Societies.

Monday, November 17th.—New York Academy of Medicine (Section in Ophthalmology); Medical Association of the Greater City of New York; Elmira Clinical Society; Hartford, Conn. Medical Society.

Tuesday, November 18th.—New York Academy of Medicine (Section in Medicine); Buffalo Academy of Medicine (Section in Obstetrics and Gynecology); Pri-Professional Medical Society of New York; Medical Society of the Counties of Kings; Binghamton Academy of Medicine; Syracuse Academy of Medicine; Oswego Medical Association; Oswego Academy of Medicine; Psychiatric Society of Ward's Island; Clinical Society of Elizabeth, N. J., General Hospital.

Wednesday, November 19th.—New York Academy of Medicine (Section in Genourininary Diseases); Woman's Medical Association of New York City (New York Academy of Medicine); Medicolegal Society, New York; Northwestern Medical and Surgical Society of New York; Buffalo Medical Club; New Jersey Academy of Medicine (Jersey City); New Haven, Conn., Medical Association.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending November 8, 1913:

Barber, John R., Captain, Medical Corps. Relieved from duty at Letterman General Hospital, Presidio of San Francisco, California, and will report for duty at Fort Huachuca, Arizona, for duty.

Blanchard, R. M., Captain, Medical Corps. Ordered to duty at Fort Porter, New York, while Major Wadhams is on leave of absence.

Darman, Lieutenant, Medical Corps. Relieved from duty about January 1, 1914, at the Field Medical Supply Depot, Washington, D. C., and after expiration of leave of absence will take the April 5, 1914, transport for the Philippine Islands.

Haine, Edgar F., First Lieutenant, Medical Reserve Corps. Granted one month's leave on account of disability, to take effect upon expiration of present leave of absence.

Hillman, C. C., First Lieutenant, Medical Corps. Now on detached service from his station Fort Myer to accompany the Fifteenth Cavalry to Fort Bliss, Texas.

Kennedy, J. S., First Lieutenant, Medical Reserve Corps. Granted leave of absence for five days.

Murdo, Howard B., First Lieutenant, Medical Corps. Relieved from duty at Fort Huachuca, Arizona, and will proceed to the Letterman General Hospital, Presidio of San Francisco, for assignment to duty.

Shaw, Henry A., Lieutenant Colonel, Medical Corps. Reported for duty as attending surgeon, Boston, Mass., on November 17, 1913. Wadhams, Captain, First Lieutenant, Medical Reserve Corps. Granted one month's leave of absence, to take effect about November 1, 1913. Walkup, O. J., First Lieutenant, Medical Corps. Left Fort Bayard, on November 1st, on one month's leave of absence. Winter, F. A., Lieutenant Colonel, Medical Corps. Will report at his new station as Commanding Officer of the Army and Navy General Hospital, Hot Springs, Arkansas.

Births, Marriages, and Deaths.

Married.

Price—Crutchfield.—In Richmond, Va., on Tuesday, October 28th, Dr. Lawrence Taylor Price and Miss Louise Crutchfield. Weige—Noble.—In Muncy, Pa., on Saturday, October 25th, Dr. Henry Stine Weige and Miss Esther Noble.

Died.

Clark.—In New York, Wednesday, November 5th, Dr. Clarence G. Clark, aged thirty-six years.

Comstock.—In Toledo, Ohio, on Tuesday, October 28th, Dr. Oliver G. Comstock, aged fifty-eight years.

Crose.—In Indianapolis, Ind., on Monday, October 27th, Dr. Samuel C. Cross, aged forty-seven years.

Fisher.—In Edwardsville, Ill., on Wednesday, October 29th, Dr. Peter Fisher, aged seventy-four years.

Hahn.—In Newfield, N. J., on Wednesday, October 22nd, Dr. H. E. Hahn, of Wallbrook, Md., aged fifty years.

Kalmerton.—In Milwaukee, Wis., on Sunday, October 26th, Dr. Edward C. Kalmerton.

Léon.—In New York, on Sunday, November 2d, Dr. Alexis Marcy Léon, aged fifty-six years.

McBurney.—In Brookline, Mass., on Friday, November 7th, Dr. Charles McBurney, of New York, aged sixty-eight years.

Myer.—In St. Louis, Mo., on Wednesday, October 26th, Dr. Jesse S. Myer, aged forty years.

O'Brien.—In Clinton, Mass., on Friday, October 24th, Dr. Phillip O'Brien.

Pedlar.—In Alameda, Cal., on Sunday, October 19th, Dr. Alfred J. Pedlar, aged sixty years.

Peebles.—In Bristol, Tenn., on Monday, October 27th, Dr. Madison T. Peebles, aged ninety years.

Rutherford.—In Kimberton, Pa., on Friday, October 24th, Dr. Robert H. Rutherford, aged sixty-three years.

Taylor.—In Oil City, Pa., on Friday, October 31st, Dr. John Erskine Taylor.

Wadhams.—In Chicago, on Saturday, November 1st, Dr. Daniel W. Wadhams, aged sixty years.

Wallace.—In London, England, on Friday, November 7th, Dr. Alfred Russell Wallace, aged ninety-six years. Way.—In Riverside, Cal., on Tuesday, October 21st, Dr. E. Henry Way, aged sixty-two years.
Original Communications.

RECENT PROGRESS IN ORTHOPEDIC SURGERY.*

By Charles Ogilvy, M. D.,
New York.

Many are the advances that orthopedic surgery has made during the past decade. In no other branch of medicine or surgery has so much progress been made in so many different lines. It is quite impossible in this short paper to intelligently discuss all the subjects relative to orthopedic surgery in which this recent advancement has occurred. The writer wishes, however, to introduce for discussion a number of important themes which are of special interest.

ANTERIOR POLIOMYELITIS.

The orthopedic treatment of anterior poliomyelitis is as interesting as it has been progressive. Oppenheimer, some years ago, first suggested fixation and rest in a plaster of Paris bed—especially during the acute stage of the disease. This has been more recently emphasized by Lange (1910) and his been practised by many. Until recently the operative treatment of infantile paralysis confined itself to tendon lengthening, tendon shortening, fasciotomies, and the manual correction of deformities. At the present time we have a number of operative procedures, all of which should be considered when treating infantile paralytic cases. These are: Arthrodesis, tendon transplantation, the use of silk ligatures, nerve anastomosis, and transplantations.

Arthrodesis.—Simple arthrodesis has been successfully employed for a number of years. A most ingenious arthrodesing operation, first reported in brief in 1901, and later, in full, in 1908, and again in 1910, is worthy of special note. This operation was devised by Whitman.1 It is especially advised for cases of paralytic calcaneus. It gives most excellent results in many cases of extreme functional disability of the foot, which we previously treated by braces and by various operative procedures with unsatisfactory results. The operation consists in first, the removal of the astragalus through an incision made on the outer side of the foot. The new articulation is then made. An arthrodesis is made between the inner surfaces of the malleoli and the sides of the os calcis and scaphoid on the inner border of the foot and the os calcis and cuboid on the outer border. The foot is then transplanted backward and fitted accurately in this new articulation. The two peronei tendons are passed through the base of the tendo Achillis and are sutured to it and to the periosteum of the os calcis. The foot being carefully held in this new position and in slight plantar flexion is so retained by a plaster of Paris dressing. This dressing remains undisturbed for five weeks.

Tendon transplantation.—In studying the literature of this subject one finds that Duplay,2 as far back as 1876, performed the first recorded tendon transplantation. Nicoladoni,3 six years later (1882), attached the peronei to the tendo Achillis in a case of paralytic calcaneus. In 1898 two hundred and seventy-four cases of tendon transplantation were reported by Eve.4 In 1899 Vulpian5 reported one hundred and sixty cases. In 1902 Lange6 advised the use of artificial tendons of silk when the lengthening of a transplanted tendon was necessary. Lange also introduced tendon transplantation to periosteum instead of transplanting the healthy tendon to the tendon of a paralyzed muscle, as had been previously done. He advised, in some cases, the passing of the tendon through a tunnel drilled through the bone, the tendon being looped back and fastened to itself at the entrance of the tunnel. He lays much stress on the preparation of the silk used. “The silk is boiled in sublimate and is then well dried for two days, under aseptic precautions. It is then cooked for an hour in paraffin (melting point 60° in a water bath). The new tendon forms along the silk, the paraffin is absorbed and replaced by connective tissue.”7

Sever,8 after a very extensive review of the subject and basing his report upon this review in addition to thirteen operations upon animals in which postoperative results and findings were carefully recorded, forms the following conclusions:

1. Tendon transplantation, per se, is at times useful.

2. Tendons lengthened or reinforced with silk are better in that they are not only stronger, but also can be used to greater mechanical advantage.

3. Silk or linen thread is an excellent material to use for lengthening tendons in suitable cases.

4. The growth of new tissue will permeate and penetrate the silk only slightly (in some cases not at all) and does not absorb it.

5. When the peritendineum and tendon sheath have been removed some foreign body is essential for regeneration to serve as a director for the new growth.

6. With the sheath and the peritendineum present and sutured no foreign body need be inserted. In this case the new growth is true tendon tissue.

7. Without the presence of the sheath and the peritendineum no true tendon tissue can be regenerated. Such tissue is merely fibrous tissue, lacking elasticity and subject to stretching.

8. The new "tendons" are apt to be larger and stronger than the resected ones, especially when silk has been used to replace the resected portion.

9. Providing the sheath and peritendineum are preserved and function allowed early, adhesions may not occur. Without the sheath adhesions may and do occur much more frequently.

Ten years ago when tendon transplantation was first introduced overenthusiasm resulted in many failures. Cases should be carefully selected and, furthermore, in relation to the muscle of the transplanted tendon, the points to be carefully considered are: 1. Its power; 2. Its loss of power when its direction of force is altered; 3. the amount of work it is called upon to do in its new relation.

Artificial silk ligaments.—The use of artificial joint ligaments of silk was reported by Lange. The first time he employed this method was in 1903. He now uses these silk ligaments in cases of drop toe,—that is, paralytic equinus. Four small incisions are made; two in front, one over the scaphoid, and one over the tibia; five centimetres above the ankle joint; two on the sides, one over the fibula and one over the cuboid. Six to eight strips of silk are firmly fastened to the periosteum of the tibia above, passed down beneath the deep adipose tissue over the capsule of the ankle joint and fastened to the periosteum of the scaphoid. Silk strands are in like manner fastened and passed from the fibula above to the cuboid below. With these two silk ligaments, one on either side, thus formed the foot is retained in dorsal flexion. "The results of the operation are good and permanent if careful aftertreatment is carried out for a year."*

Nerve transplantation and nerve anastomosis.—These procedures are still in the experimental stage. Favorable results of nerve grafting in cases of infantile paralysis have been reported by Spitz, Ballance and Stewart, Rivers and Head, Langley and Anderson, Killington and Dunlap, Taylor and Peckham, Tubby and Sherren, Young, and others. These have, in most instances, been isolated cases rather than groups of cases. Warrington and Murray state that there have been few successes and many failures. The writer is also of this opinion. Generally speaking, one is unable, at the present time, to report favorably upon this subject. Good results, however, have been obtained, and the possibilities are far reaching.

CONGENITAL DISLOCATION OF THE HIP.

Congenital dislocation of the hip was looked upon about twenty years ago as an irremediable condition. At that time (1890) Hoffa, of Berlin, advised the open method of reduction. In 1895 Lorenz modified this open operative procedure. During the next five years (1890-1900) Lorenz began to treat cases by the closed method of reduction. In 1900 he published some of the results which he had obtained. In 1905 F. Calot, of Berck sur Mer, published his Traite pratique de technique orthopedique, technique de traitement de la luxation congenitale de la hanche, in which he described at length his modification of the Lorenz operation. From the experience of the writer the results obtained by Calot's operation are even better than those from the Lorenz method. The outline in brief for this treatment is as follows:

The patient is anesthetized and placed upon the table. The pelvis is firmly fixed by the assistant while the operator flexes both the thigh and knee to 90°. At the same time traction directly upward is made with the knee in this flexed position. There is little or no abduction, neither is there any rotation of the limb. While this manipulation is being carried out—probably by two assistants, one holding the pelvis down upon the table and the other making traction upon the thigh directly upward—the operator places his thumbs beneath the great trochanter and presses upward. By this means he is enabled, in the younger patients, to slide the head of the bone into the acetabulum, the replacement of the head being distinctly felt when the reduction is made. When this fails a second manoeuvre is that of adding to the treatment a slight rotation outward with a simultaneous abduction of the limb. If this fails to reduce the dislocation, Calot advises that the patient be laid upon the well side and the leg be adducted as far as possible—the knee being still held at right angles and traction being kept up as before—at the same time rotating the limb slightly inward. The operator, with his thumbs upon the great trochanter, is enabled by such pressure to reduce the dislocation. A plaster of Paris spica is then applied with the limb in 70° of flexion and 70° of abduction without any rotation. This spica, including the foot, must be applied snugly and firmly over cotton—which cotton is itself bandaged tightly to the body. Calot advises this first spica to remain undisturbed for three months, after which a second is applied in which the leg is rotated inward, at the same time reducing the abduction to a position which can be obtained without force. The second spica remains on for a couple of months. The more favorable cases do not require a second spica. Of this operation Calot says: "Soumise a un bon traitement la maladie guerit et l'état de la hanche revient normal ou sensiblement normal." He goes on to state that the condition in unilateral cases is always cured in children under seven years of age (one hundred per cent.) In patients from seven to twelve years of age nine out of every ten are cured (ninety per cent.); from twelve to fifteen years of age, three in every four are cured (seventy-five per cent.); over fifteen years of age the difficulty becomes almost insurmountable. However, by a long preparatory treatment one might obtain success. In bilateral dislocations one must lower the respective ages three years. Thus the chances of reducing a double

dislocation in a patient seven years old are nine to ten (ninety per cent.). In those between seven and twelve years of age the chances of reduction are three to four (seventy-five per cent.). Above twelve the chances are the same as those in the unilateral cases in patients fifteen years of age. The age of choice is between two and three years. The writer, from personal experience and from the experience of his confrères, considers that such statistics can hardly be accepted. In other words, he does not believe that one hundred per cent. of cures are obtained in unilateral cases in patients seven years of age and under. Nor do we believe that one hundred per cent. of cures are obtained in bilateral cases in patients under four years of age. By cures we refer to a perfect anatomical and functional result. The question then naturally follows, What results may one expect? To which the writer replies that between eighty and ninety per cent. are cured in unilateral cases in patients between two and seven years of age. In bilateral cases one may prognosticate cures in children between these same ages in about fifty per cent. of the cases. To these statements one might add that a number of cases in which perfect anatomical and functional results were not obtained the patients were much improved by reason of the dislocation being changed from a posterior to an anterior one with the head of the bone taking up its position under the anterior inferior spine. In this position the functional result may be designated as good.

In reporting upon the results obtained by the Lorenz method, P. Redard\(^{9}\) stated that in operations upon children between two and four years of age, in eighty-five to ninety per cent. of the unilateral cases and in thirty per cent. of the bilateral cases, anatomical and functional cures were obtained. It is interesting to note that among four hundred and fifty of the early cases which Lorenz reported upon there were eleven cases of fracture of the neck of the femur, three cases of fracture of the pelvis, three cases of perineal paralysis, three cases of crural paralysis, three cases of sciatic paralysis, one case of rupture of the femoral artery, and one case of gangrene necessitating amputation. These complications were undoubtedly due to the great amount of force which was used in the abduction of the limb and of the attempted reduction in this position. The Calot method of abduction practically eliminates the probabilities of any such unfortunate complications by reason of there being no forced abduction of the limb.

THE OPERATIVE TREATMENT OF POTT'S DISEASE.

For many years the idea of immobilizing the vertebra in Pott's disease by means of fixing the spinous processes firmly together has been considered. Hadra,\(^{10}\) in September, 1891, discussed the advisability of wiring the spinous processes together. Phelps and others, subsequent to this date, attempted and obtained fixation in this way. It was found, however, that the wire cut through the bone in too many instances to justify the advisability of performing this operation, so that it was discontinued.

Doctor Lange,\(^{11}\) in May, 1910, read a paper before the American Orthopedic Association upon Support for the Spondylitic Spine by Means of Buried Steel Bars Attached to the Vertebrae. He used tin plated steel wire five millimetres thick and ten centimetres long. The ends of these splints are wired into place. They are placed on either side of the spinous processes. Strong paraffin sublimate silk is used to fasten the rods to the spinous processes. The steel rods are inserted into an incision through the muscles as deeply as possible and close to the bone to the right and left of the spinal column. The skin incision is sewed up and drained at the upper end of the wound for forty-eight hours. A plaster of Paris jacket is applied which is not removed until six weeks after the operation. After which a celluloïd corset is worn. In concluding the presentation of this subject Lange, though admitting that the cases had been too few to draw very definite conclusions, advises the continuance of this operative procedure. Owing to the difficulties, however, associated with the preparation of the metal, and so of assuring good results, this treatment has not been generally followed, nor can it be advised.

Bone transplantation for Pott's disease.—In the Journal of the American Medical Association of September 9, 1911, F. H. Albee first reported upon this subject. A curved incision is made down the back which passes by the side of the spinous processes of the vertebrae involved. The skin flap is turned aside and the spinous processes are reached. The cartilaginous tips of the spinous processes are split in the centre, as is also the super spinous ligament, leaving each part of it attached to the halves of the spinous processes. The inter spinous ligaments are split in two equal parts to a depth of about three quarters of an inch. The spinous processes themselves are then split with a chisel to a depth of about three quarters of an inch. Thus a wedge is formed into which the transplant is fixed by interrupted sutures of kangaroo tendon. These are passed through the super spinous ligament. The sutures are drawn snugly over the graft posteriorly. The graft is taken from the anterior surface of the tibia. This is done without changing the position of the patient by flexing the knee upon a sand bag. The length of the graft will depend upon the number of vertebrae involved. Its breadth is from two thirds to three quarters of an inch and its thickness from one third to one half an inch. The patients are kept in a recumbent position for a few weeks (from six to seven), after which Albee states that they may be allowed up without any spinal brace.

Hibb's operation for Pott's disease.—In June, 1911, this operation was first reported upon. It consists in cutting down upon the spinous processes, stripping the super spinous ligament and the periosteum from either side of the spinous processes involved, as well as one above and one below this area. The spines being thus laid bare of periosteum and superimposing tissues, are broken down, one upon the other, by means of chiseling half way through the upper part of the spinous process and making a green stick fracture

\(^9\)P. Redard, Zeitschrift für orthopädische Chirurgie, Bd. xxx, h. 1-2, 1912.

\(^{10}\)Dudley's Texas Medical Journal, September, 1891.

\(^{11}\)American Journal of Orthopedic Surgery, viii. No. 2.
of its remaining half. The tip of the spine is de-

nuded and planted firmly in the gap made by the

breaking down of the spinous process immediately

beneath it. The spines of all the vertebrae involved

and, in addition, one above and one below this area,

are so treated. They are held firmly in position by

the periostum and superjacent structures which

are firmly drawn together across them posteriorly.

Hibbs has shown by radiographs, as a result of

this procedure, the formation of a definite bony

bridge by means of which both immobilization and

protection of the diseased vertebrae are obtained.

It is too soon to estimate the true value of these last

two operations mentioned. In comparing the two,

and having performed both operations several times,

the writer would be inclined to place more confi-
dence in the results obtained by Albee's method.

He would advise, however, that the aftertreatment

of these patients should be very carefully carried

out, and that a spinal support—preferably of plaster

of Paris—be continued for at least a year after the

operation. A number of serious complications have

followed and full reports upon these cases will

alone enable us to know definitely what value to

place upon such operative procedures, and in which

cases these operations should be advised. Such

treatment is, however, a decided step in advance

and there seems but little doubt that the length of

time of treatment will be materially shortened by

these methods.

MOBILIZATION OF ANKYLOIZED JOINTS.

Mobilization of ankylosed joints has been a sub-

ject to which much thought and a great deal of

work has been given. Helferich, in 1893, excised

the condyle of the inferior maxillary bone in a child

and inserted within the articulation a flap from the

temporal muscle. In 1902 Gluck used the skin flap

for the same purpose. In 1902 Orlow inserted

metal plates and also gold foil. Muscle flaps have

been used by Quenu, Albarran, Nélaton, Delbet,

Murphy, Hoffa, and others in both the hip and

knee joints. Murphy has advised the use of a flap

of fascia covered with a layer of fat from which

he reports good results. Weglewski,12 in 1907, re-

ports a case in which he transplanted the cartilage

from the seventh rib into an ankylosed elbow joint

by which he obtained sixty to seventy degrees of

motion.

One who has done considerable work in this new

field of operation is Dr. William S. Baer, of Balti-

more. The writer has seen the results in a number of

his cases. He uses the membrane from a pig's

bladder, which is chromized to remain intact for

about forty days.

In the knee joint two lateral incisions are made

along the side of the patella. The patella is thor-

oughly freed from the femur, as is also the tibia

from the femur. All new bone formation is re-

moved and complete mobility obtained. The pig's

bladder membrane is inserted into the joint so as

to completely prevent contact of any of the raw

surfaces one upon the other. The membrane is

sewed into the joint by catgut sutures. The wound

is entirely closed and the leg is put up in a cast.

Passive motions are begun within seven to ten days.

12Zentralblatt für Chirurgie, April 27, 1907.

In the hip joint the joint is approached through an

anterior incision. The capsule is cut through, the

head separated from the acetabular cavity, exostal

growths are removed, the acetabulum is curetted,

and the surface of the head of the bone and that

of the acetabular cavity is made as smooth as pos-

sible. The pig's bladder membrane is placed be-

tween the head of the bone and the acetabulum and

is bound tightly about the neck, where it is sewed

with catgut sutures. The wound is then closed up

tightly and the leg is put up, usually, in about

twenty degrees of abduction. The first dressing is

made after about eight days, when passive motion is

begun. Doctor Baer12 concludes in his first presen-
tation of this subject as follows: "Our results of

permanent motion attained by the use of chromized

pig's bladder in ankylosed joints have been such as

to make a more exhaustive study of the method

advisable." Later results are still more commend-

able.

ROTARY LATERAL CURVATURE OF THE SPINE.

In the New York Medical Journal of June

24, 1911, and of April 27, 1912, the subject of

rotary lateral curvature of the spine was dis-

cussed by Abbott. The method of treatment was

described at length and the results in some eighteen

cases were reported upon, with photographs repre-
senting the condition before and after treatment.

The results as reported were so remarkably good,

especially in the cases of long standing fixed curva-
ture in which bone change had taken place, that a

great deal of interest was aroused and a number of

us journeyed to Portland, Maine, to obtain as

much information as we could upon this subject.

These patients are treated with plaster of Paris

jackets which are applied in flexion instead of in

extension as had previously been done. The jacket

is applied in a horizontal position in a gaspipe

frame, within which a hammock is swung. The

patient is swung upon this hammock face upward.

The body is allowed to flex forward by its own

weight. The hammock, being shorter on one side

than the other, allows the short side to press against

the butting ribs. The back of the neck is rested

upon a strap of webbing. The buttocks are sup-

cported by a cross bar. Straps are then applied

around the body to pull it in any direction desired.

Three or four such straps are used. The object of

this method of horizontal suspension with side trac-
tion straps is by this means to reverse the curves

of the spine and place them in the opposite direc-
tion as far as possible. When this has been ob-

tained the plaster of Paris is applied—care being
taken to carefully pad the patient with felting, es-

pecially back of the low shoulder, over the sacrum,

over the spinous processes of the ilium, over the

prominent ribs of the front of the thorax, under both

arms, and over the convexity of the ribs.

After a thick plaster of Paris jacket has been

applied two windows are cut in the jacket—one

behind and another in front. The one at the back

occupies the area where the ribs were depressed to

allow the body to come over toward this side. On

the other side of the jacket the other window is

cut in front, which allows the ribs that bulge pos-
teriorly to push forward. Felt is crowded in over

the convexity posteriorly, and this is added to every few days. In the cases which Abbott reported the length of time taken to produce complete correction which he claims to have obtained, was from ten days to six weeks—the average time being three weeks.

In the New York Medical Journal of April 27, 1912, the same Journal in which Abbott's last article appeared, there was also another by the writer entitled Rotary Lateral Curvature Based Upon the Report of Results Obtained.

My conclusions at that time have since been substantiated. They are, in brief:

1. That rotary lateral curvature of the fixed type, developed in childhood and persisting in adolescence, cannot be perfectly cured.
2. That the general condition of the patient can be much improved.
3. That the anteroposterior postural deformity can be corrected.
4. That the lumbar lordosis can be corrected.
5. That the lateral deviation of the body can be corrected.
6. That the lateral deviation of the spine is corrected in earlier cases.
7. That the rotation of the vertebrae may be improved but not corrected.
8. That the results obtained by the use of the plaster jacket applied by the Abbott method in flexion, with corrective felt pads, are very satisfactory in that we are enabled to obtain the results above enumerated in a shorter time (within six months) than by any other method of treatment heretofore practised.

40 East Forty-first Street.

OBSERVATIONS ON INOCULATION THERAPY.*

By Martin J. Synnott, A. M., M. D.,
Montclair, N. J.

President, New Jersey State Pediatric Society; Pediatrician to St. Vincent's Nursery and Babies' Hospital, Montclair, N. J., and to St. Mary's Hospital, Orange, N. J.; Ex-President, Board of Managers, Essex County Isolation Hospital, etc.

Sir Almroth E. Wright has made the prediction that "the physician of the future will be an immunizer." We might define an immunizer to be one who has mastered the principles of immunity, as discovered and elaborated by Pasteur, Metchnikoff, Wright, Ehrlich, Leishman, and others, and is prepared to apply them to the prevention and cure of disease. The successful application of his studies on immunization, notably his antitoxin inoculation, has attracted the attention of the whole civilized world to Wright and his brilliant coterie of associates and assistants in the laboratories of the inoculation department of St. Mary's Hospital, London. Much has been written and spoken for and against the method of vaccine therapy which he has elaborated, but the consensus of opinion of scientific men is that by proper bacterial inoculations in suitable cases we are really able to raise the antibacterial power of the blood, in this way success- fully combating infections. Wright's discovery becomes, therefore, "the most valuable asset in medicine," and it has produced and it is destined to produce results of great importance in the domain of practical medicine.

Many men have undertaken the administration of bacterial vaccines who are not qualified; and criticisms are sometimes offered by physicians whose disastrous failures have been due entirely to their own inexperience and lack of knowledge of the fundamental principles of inoculation therapy. It is a complex and difficult subject which requires careful theoretical study and sound judgment, founded on a considerable clinical experience. The practitioner who undertakes specific inoculation without such painstaking preparation is not only doomed to disappointment for himself, but may seriously aggravate his patient's condition. In this connection it must not be forgotten that vaccine therapy is quite different from and much more complex in its administration than serum therapy; although with our recently acquired knowledge of anaphylaxis—the term used to describe the alarming symptom complex occasionally met with after the injection of a serum—we have found that even successful serological work is not always plain sailing.

As to the requirements for the successful application of his new therapeutic method, Wright has given us the following classical summary: "The medical man who has recourse to vaccine therapy ought to have familiar acquaintance with the microbes which affect the human body. He ought to appreciate the fact that vaccines owe their efficacy to the reaction they set up in the tissues, and not to any action exerted directly by the vaccine upon the invading microbe. He ought to have mastered the general principles of immunization. He ought to know in connection with each vaccine the minimum effective dose, i.e., the dose which gives the minimum immunizing reaction without any intervening negative phase; and the medium or average dose, i.e., the dose that gives, after a negative phase, a more powerful immunizing reaction. He ought to know the general conditions which affect the sensibility of the organism. He ought to understand how to adjust the dose to the requirements of the individual patient. And he ought to have a knowledge of the conditions which obtain in the focus of infection, and of the methods of circumventing the difficulties which are introduced by these conditions" (1).

The writer has been devoting such time as he could spare from the demands of an exacting practice for the past four years in an attempt to qualify under these requirements. And it is with the hope that his observations and experience may benefit others this paper is offered.

BACTERIOLOGICAL REQUIREMENTS.

In order to select a suitable vaccine for a given case, we must first determine accurately what microorganism is the cause of the disease, because a vaccine is specific and has no effect except in combating its own species. It is sometimes possible for an experienced immunizer to do this from the clinical picture and symptoms without recourse to laboratory methods, because many lesions are regu-
larly associated with certain bacteria; thus the staphylococcus is, in the majority of cases, the cause of boils, carbuncles, osteomyelitis, syphilis, acne, suppuring acne, and often eczema, whitlow, occasion-ally infective endocarditis, and septicemias; the streptococcus is known to be the cause of most forms of infectious cellulitis, lymphangitis, pur-

eral septicemia, erysipelas and septic endocarditis; the tubercle bacillus is the causative infection in many chronic joint, glandular, and osseous swellings, many skin lesions, tuberculous peritonitis, and frequently of infections of the genitourinary system, besides phthisis. Where the diagnosis cannot be thus easily determined, the discharge from the affected part of the organism must be examined microscopically, and if more than one organism is observed, cultures must be made until pure growths are obtained. In this latter case we may either use a mixed vaccine or select the bacillus which is the most probable pathogenic agent, as evidenced by its greater viru-
tence or the clinical symptoms (2).

The determination of the causal microbe in septic endocarditis and other septicemias may in the ab-
sence of an obvious lesion necessitate blood cultures. Likewise in infections of the bladder, ureters or genitourinary tract, catheter specimens of urine must be obtained and cultured in the laboratory. Cultures from the urine are often of value in gen-

eral septic conditions, as sometimes the microorgan-

ism causing the disease, particularly the streptococ-

cus and the staphylococcus, may be found in the urine when it cannot be isolated from the blood.

The possibility of a double infection or of a mixed infection must always be borne in mind, particularly

where no improvement takes place in the clinical symptoms, although the case is one which we would expect to respond promptly to inoculation therapy.

Thus streptococci may be present in tuberculous glands, causing suppuration; or pneumococci may complicate pulmonary phthisis. In such cases the secondary infection must also be treated specifically before a cure will result. Failure to recognize this fact explains many of the failures and contradictory reports made by beginners and the inexperi-

enced.

**IMMUNITY.**

One cannot hope to apply vaccines to the pre-

vention or cure of bacterial diseases intelligently

without a comprehensive knowledge of the general principles of immunity. It is a well known fact

that when an individual recovers from an infectious disease he is ordinarily in no danger of contracting it afresh, and that this nonlability continues for a longer or shorter period. There is no plausible explanation of this phenomenon other than that the infected system develops a resistance to the action of the invading pathogenic microbes which it did not originally possess, and that complete recovery is due to this resistance becoming strong enough to overcome and destroy these organisms (3). The problems involved in the development of such re-
sisting powers have usually been studied under the term "immunity," under which we include not only the nonsusceptibility of an individual to a given dis-

ease and the power to resist infection, but also the mechanism by which a cure is effected.

According to the hypothesis of Wright, when a patient recovers spontaneously from a bacterial in-

fection his cure is the result of immunizing re-
sponses evoked by the setting free of bacteria or their products from the focus of disease into the ad-

jacent lymph or blood stream of the individual, to which process he gives the name of "autoinocu-

lation." Wright has demonstrated that it is possible to produce artificially in the human organism such immunizing responses, and the elaboration of anti-

bacterial elements in the tissues by the hypodermic inoculation of bacterial vaccines which are derived from (autogenous) or correspond to (exogenous) the infecting microbes. This process he calls ther-

apeutic immunization.

The microbes in the vaccine are devitalized so 

that they cannot multiply after being injected into 

the tissues. If the dose has been properly regulated the inevitable result of the inoculation is the manufac-

ture at the site of the injection of antibacterial substances, or "opsonins," generated by the organ-

ism on a scale which is more than adequate to bring about the destruction of the bacterial elements in-

corporated in the vaccine. The surplus of the specific antibacterial substances thus elaborated is 

carried by the blood stream to the focus of infection which we desire to benefit, stimulating phagocytosis and bringing aid to the defensive forces of the orga-

nism, which were perhaps ineffectually combating the invading microbes. Thus the victory which the uninfected tissues have won over the dead microbes of the vaccine will in this way lead up to a victory of the infected tissues over the microbes they have to combat (1). This is active immunity.

In passive immunity, on the other hand, it is first 

necessary to immunize an animal actively by inocu-

lating it with bacteria or their products, and when

the protective substances have been produced in sufficient amount the serum of the immune animal is 

used for curative purposes upon individuals at-

tacked by the disease for which the serum was 

produced. This is known as serum therapy, the application of which produces passive immunity.

Successful specific sera have been thus produced in diphteria, tetanus, epidemic cerebrospinal men-

initis, and dysentery—rather a short list.

Vaccines are useful in combating bacteria which 

contain the poisonous substances within themselves, the so called "endotoxines," types of this class being the staphylococcus and streptococcus; whereas 

serums are ideally suited for the "exotoxic" micro-

organisms of which the Klebs-Loeffler bacillus is the type. Bacteria of this latter class, while they 

themselves remain localized in the tissues first at-

tacked, produce virulent toxines from the media in 

which they grow, and these poisonous substances 

are absorbed into the blood, are very easily diffused through the body, creating serious havoc in the 

various tissues and organs with which they come 

in contact and produce the clinical symptoms of the disease. In infections from bacteria of this class 

the chief danger to the patient is from these toxines.

The endotoxines, on the other hand, are set free 

in the body only by the death and disintegration of 

the bacteria, and are not diffused by the blood 

stream as in the case of true toxines.

In acute disease, if one is to use a vaccine at all 

successfully, it must be given early, because the 

protective antibacterial substances are slowly pro-
duced. In exoteric infections, like diphtheria, the poisons form so rapidly and are so quickly diffused throughout the body that the damage might easily be done before the immunizing mechanism of the body could be sufficiently stimulated by the vaccine inoculations to destroy the invading microbes. Here, of course, serum treatment is indicated, because by neutralizing the poison damage to the various organs and nerves is prevented. Prompt administration is also important in administering a serum, because if we wait until the organs or tissues have been damaged by the toxines, the antitoxines cannot be expected to undo such harm.

It is evident, we think, that the number of diseases to which serum treatment will prove to be applicable is likely to remain small, however striking its success may be in the cases where it can be used. Thus, both its aim and the scientific basis on which it rests distinguish it completely from Wright's plan of inducing active immunity by therapeutic inoculation.

It has recently occurred to the writer that in certain infections it might be permitted to use both a serum and a vaccine, the former to neutralize the toxines and the vaccine to stimulate phagocytosis. I have never heard of this being done, but under suitable conditions I do not see why it would not be a proper expedient.

In connection with our studies on immunization, it is well to bear in mind that according to Pasteur there is no such thing as absolute immunity, because if the infection is large enough and virulent enough even an immune individual will contract the disease.

**The Opsonic Index.**

The direct effect of a properly administered inoculation is to produce an increase in the blood of certain substances known to exist there, but not isolated, to which Wright has given the name of "opsonins." These substances act upon the bacteria in some way so that they become a ready prey for the white corpuscles, and indirectly increase the phagocytic power of the blood. The "opsonic index" is the expression of the measure of the phagocytic power produced in a sample of washed leucocytes by the serum of the individual in question, as compared with the phagocytic power induced in a similar sample of leucocytes by the serum of one or more healthy individuals. The technic devised by Wright for the estimation of the opsonic index is difficult to acquire, and much patient endeavor and practice are necessary before one is able to secure trustworthy and satisfactory results. It consumes time, and special laboratory apparatus is necessary. It is of value only when estimated by an expert opsonist.

In a not inconsiderable proportion of cases it is essential to success that the dose of a vaccine shall be controlled and regulated by measurements of the opsonic index. This applies particularly to difficult cases—especially pulmonary tuberculosis and severe acute infections, such as septic endocarditis.

A rise in the opsonic index subsequent to an inoculation is always favorable, but in cases of some lesions—for instance, carbuncles—the severe negative phase following a large dose will very often cause much liquefation of the diseased tissues, which is at times of great advantage in hastening a cure by rapidly throwing off the slough. This phenomenon explains why in furunculosis certain patients get better during the negative phase. In phthisis pulmonalis, on the other hand, patients have shown high opsonic indices, even though doing badly. This seemingly contradictory phenomenon is explained on the theory that in such cases there is probably some complicating infection—perhaps streptococcus or pneumococcus.

The opsonic index, in expert hands, is one of the most valuable and positive aids we have in the diagnosis of incipient phthisis and in the differential diagnosis of obscure diseases where the causal microbial agent cannot be determined by ordinary bacteriological procedures; as, for example, in deciding whether the pathological condition in an infected joint is due to tuberculosis or to the gono-

**The Positive and the Negative Phases.**

Following a bacterial inoculation there is usually a drop in the opsonic index of the patient, accompanied by characteristic clinical symptoms. This is the so-called negative phase. The length of this phase and the clinical symptoms depend upon the size of the dose. The clinical symptoms may be either subjective or objective, or both; the subjective symptoms may include one or all of the following: General malaise, a "seedy" feeling, increased tenderness and pain at the site of the lesion, or in the limbs, or joints, lassitude, headache, nervous irritability, drowsiness, and in bladder cases increased frequency of micturition. The objective symptoms ordinarily observed are an increase in the discharge, swelling, or congestion, in cases of acne an increase in the number of foci of infection, and in bladder cases perhaps more cloudiness due to increased activity on the part of the infective microbe. There may be occasionally a slight rise of temperature. An abrupt drop in the temperature from 103° or 104° F. to subnormal may indicate an excessive dose. Occasionally rigors, high temperature, and vomiting may follow an excessive dose. Or if the dose has been very small the clinical symptoms may be absent altogether.

This state is then followed by a rise in the opsonic index, indicating an increase in the opsonic value of the blood, providing the patient has the power to react. Clinical evidences of improvement are also apparent. A state of general invigoration ensues which is quite marked. The patient feels better and very gleefully says so. The rise in the opsonic index following the negative phase Wright calls the "flow": the subsequent decline in the index toward normal he designates as the "ebb": the two together constituting the positive phase. It is when the ebb becomes manifest that the inoculation should be repeated.

**Dose.**

Wright has determined the dose of various vaccines accurately by a long series of experiments, including many thousands of estimations of opsonins and agglutinins, and careful observations of the clinical symptoms during the negative and positive phases, following inoculations. From
the hundreds of men who have gone to London to study under him he has had exceptional opportunities to select assistants of unusual ability who have ably aided him in these researches. One should not attempt to use a vaccine until he has learned the range of doses of such bacteria, where this has been definitely established, and the methods of determining the dose suitable for a given case.

The amounts recommended by the commercial houses in the United States are, as a rule, too large, so much so that the beginner who takes their printed literature as his guide is apt to be disappointed with the results, if indeed he does not get into serious difficulties. It is a fact that most men who use vaccines in this country are administering excessive doses, a fact which explains the many failures which we hear of or read about from time to time. One must not forget that an overdose of bacterial vaccine may be as injurious as an overdose of arsenic or strychnine; while an insufficient dose, on the other hand, may be as ineffectual as too small a dose of quinine in a bad case of malaria.

In quite a long list of vaccines, thanks to Wright's investigations, it is now only a matter of memory to learn the doses of the vaccines most frequently used from the "minimum effective" to the "medium or average" dose. The minimum effective dose is to be administered in all acute febrile conditions, such as phthisis pulmonary, where autoinoculations are taking place, and where even a very short negative phase might lead to disastrous activity on the part of the invading microorganism, making possible the involvement of tissues previously unaffected, and the initiation of fresh foci of infection in hitherto uninvolved areas. In chronic and afebrile infections, on the other hand, we would use a medium dose because we know that after a negative phase a longer period of increased immunity is secured. Unless the positive phase is preceded by a negative phase, it will be of short duration; in other words, the longer the negative phase, the longer the positive phase will be, but this holds true only up to a certain point, beyond which attempts to lengthen the positive phase by increased doses may ultimately result only in the "summation" of our negative phase when no positive phase accrues at all.

The best results are obtained, therefore, where a negative phase, giving at the most only mild subjective symptoms and lasting not longer than from twelve to twenty-four hours, is followed by a positive phase lasting from three to ten days. Such a result when the index is chartered is designated by opsonists as the "ideal curve." This dictum applies to all cases except general infections with fever when bacteria are present in the blood stream. In such cases even a very brief negative phase may do harm, and if vaccines are to be used at all, they should be given in minimal doses, at more frequent intervals, perhaps, but always by an expert able, if necessary, to control them by estimations of the opsonic index.

When our methods become more perfect and exact, it may be possible to so determine our dose as to avoid the negative phase. It is always wise to give as an initial dose an amount well within the limits of safety, and to gradually and cautiously increase it if the symptoms so warrant until, if necessary, large amounts are administered.

Where the minimum effective doses are used, as they should be in all severe febrile infections, there is no negative phase, but the immunizing response elicited is very brief; hence the inoculations must be more frequently repeated, in some cases daily injections being permitted. After larger doses the inoculations are to be repeated when the positive phase symptoms, as indicated by the careful interpretation of the clinical symptoms, or in doubtful cases by the estimation of the opsonic index, are no longer apparent. In practice this varies from three to fourteen days.

An overdose will during the negative phase increase the objective symptoms of the disease; in treating acute infections this is to be avoided if possible. We should aim, ordinarily, to get only mild subjective symptoms such as malaise, and to avoid all objective symptoms.

A moderate negative phase in strictly localized or chronic infections does no harm because the opsonic content of the circulating blood does not immediately affect the disease focus. On the contrary, the local reactive inflammation of this phase may do good by flushing the lesion with blood and an increased outflow of lymph, whereby a greater quantity of the blood's protective substances is carried into the infected area and thus healing tends to result.

In determining the dose it must not be forgotten that a marked difference occurs in different strains of bacteria. Thus, a satisfactory immunizing response may be obtained from a vaccine in doses of two millions, while other vaccines made from different strains of the same bacillus may require as a dose from forty to fifty millions; in other words, the dose will vary according to the virulence of the strain used in preparing the vaccine. This applies particularly to the gonococcus, the streptococcus, and the colon bacillus. At St. Mary's Hospital, London, all the strains of bacteria used in making vaccines have been frequently tested as to their immunizing power by careful clinical and blood tests, and their therapeutic value is thus definitely determined. In no laboratory in the United States, so far as is known to the writer, is this done, and for this reason he prefers to employ Wright's vaccines when he uses stock preparations to the ones put on the market by the commercial houses in this country, which are made from strains which have not been tested therapeutically, because of the lack of clinical facilities, or of men competent to carry out such experiments.

**WRIGHT'S DOSES.**

</table>

In the matter of dose, it is the experience of most conservative immunizers nowadays that smaller doses are to be preferred, at least in the be-
beginning of the treatment, to the very large doses reported, sometimes disastrously, in connection with the earlier experiments with inoculation therapy. Generally speaking, the more severe the infection and the more pronounced the clinical symptoms, the smaller should be the dose of vaccine employed. It is now entirely possible to effect a cure by vaccine therapy without once inducing the toxic symptoms associated with the earlier attempts at immunization, and still frequently seen after inoculations by the ignorant and inexperienced. A toxic dose should never be given, and is always to be avoided if possible. The initial dose should, with rare exceptions, be small, and the increase gradual. This conservatism applies also to the frequency of the inoculations; because undue frequency may, like an overdose, do harm by inducing a severe or protracted negative phase. If at any time it is thought best to omit an inoculation, salt solution may be substituted for the vaccine, in order to hold the patient's attention.

Robust individuals require larger doses than thin and delicate patients. As in the administration of salvarsan, the body weight may be taken as a guide to the dose.

Children, of course, require much smaller doses than adults.

Bacterial vaccines are standardized in such a manner as to contain in each c. e. a specified number of microbes, except in the case of Wright's tubercle vaccine, where each c. e. contains a specified weight of the powder obtained by the comminution of tubercle cultures.

**Artificial Autoinoculation.**

When a patient fails to recover from a bacterial infection this may be due to excessive autoinoculations, causing a profound or permanent "negative phase," with lowered resisting power in the blood, making possible the rapid extension of the disease processes; to an inadequate or tardy immunizing response; or to the fact that the infective bacteria occupy a nidus so sheltered from the bycircular blood that the antibacterial agencies (opsonins) in the blood do not have free access to them, and thus phagocytosis is interfered with.

Artificially induced autoinoculations are destined to prove important factors in the treatment of many diseased conditions in which vaccine inoculations are impossible or are contraindicated, and an interesting field for experimental therapy along these lines is thus opened to the intelligent and observant physician. Moreover, it is important in treating all infectious diseases to find out, if possible, before resorting to bacterial inoculations to produce active immunity, what the body itself is capable of doing and to what extent extraneous circumstances such as exercise, massage, osteopathy, passive motion, Bier's apparatus, poultices, etc., may influence these attempts on the part of the body. The increased circulation thus induced does good by carrying away from the focus of infection some of the bacteria or their products into the general circulation, thus inducing an autoinoculation. In phthisis such autoinoculations are very frequently taking place, and may be induced by coughing, talking, deep breathing, or exercise (6). This explains why in phthisis the opsonic index is often high or variable, and also why the opsonic index taken before and after exercise or massage is such a valuable diagnostic guide.

Care must sometimes be taken to prevent excessive autoinoculations, which might do the patient serious harm by inducing a prolonged or severe negative phase, thus making possible the rapid extension of the disease. The agents at our disposal for this purpose in subacute or chronic cases are carefully graded or restricted exercise; and in acute febrile cases absolute rest in bed, quiet breathing, no talking, and occasionally the local application of ice. For this reason poultices to the chest in a severe pneumonia may do harm by producing a summation effect in the negative phase.

The thorough comprehension of the phenomena of autoinoculation enables us to explain many clinical problems hitherto obscure. An intelligent understanding of its *modus operandi* will be a valuable aid to the general practitioner.

In chronic conditions and in all nonfebrile conditions, in which bacterial vaccines are indicated, much good may be accomplished by periodic autoinoculations, artificially induced by any of the various measures at our command for the production of an increase of circulation through the infected part. Many of the cures attributed to osteopathy are undoubtedly explained in this way.

In comparing the respective advantages of autoinoculation and inoculation with bacterial vaccines as a means of treatment in bacterial infections, we must not forget Wright's warning that in the former method we use unmeasured doses of living cultures and therefore it must be uncertain and never can be altogether dissociated from risk.

**Lymphagogues.**

Successful results can be obtained from inoculation therapy only where an efficient lymph stream can be conducted through the foci of infection. Unless the blood stream with its antibacterial substances or opsonins has free access to the infected area, an increased opsonic index may not ameliorate the symptoms. The walls of an old sinus with a poor blood supply by reason of pent up discharge, due to obstruction to outflow, or coagulation, offer the infective microorganisms a highly suitable nidus in which to multiply. Again the contents of an infected cavity, whether it be the peritoneum, pleura, or an ordinary abscess, may be low in protective substances, while the bycircular blood may contain an excess. Sinuses must therefore be flushed, abscesses drained, and poultices, massage, or Bier's apparatus employed to increase the local blood supply. Lymphagogues are indicated in such cases. Flushing the sinus with a solution containing four per cent. of sodium chloride and one per cent. of sodium citrate in sterile water promotes by its hypertonicity increased osmosis through the sinus walls, and a more copious flow of lymph ensues. Inasmuch as the sodium citrate prevents coagulation, the lymph, rich in protective substances, will find its way to the surface unagulated. In the case of a cavity, drainage is followed by the introduction of fluids from the blood, containing an excess of protective substances, and the cavity is quickly healed (2).
THE WIDE SCOPE OF VACCINE THERAPY.

The field for vaccine therapy is almost as wide as that of medicine itself; some idea of its scope may be obtained from the following enumerations: 1. Inflammatory trouble at the roots of the teeth with toothache, pyorrhea alveolaris, caused by the ordinary streptococci of the mouth; 2. pruritus ani, in which disease a platinum loop applied to the seat of irritation brings away astonishing numbers of microbes, invariably staphylococcus and pseudodiphtheria, and occasionally tetragenos; 3. hay fever; 4. x ray dermatitis; 5. urinary calculus, which has been found to be associated with the presence of staphylococci in the urine; 6. indigestion, vomiting, and flatulent distention of the stomach, so often seen in early phthisis where pyorrhea alveolaris is a frequent accompaniment; 7. epilepsy, in which disease the symptoms may be due to a bacterial focus standing in connection with the nervous system; 8. pancreatic diabetes and Graves’s disease, and other diseases due to the faulty functioning of some organ which may ultimately be traced to a bacterial infection from a coliform bacillus or the staphylococcus. In this connection Wright has suggested that glycosuria and carbuncle, which we have always supposed to be related as to cause and effect, may perhaps in some cases at least be merely two different manifestations of a staphylococcal infection; 9. enuria, which is sometimes due to an unsuspected coli infection of the urine (3).

AUTOPGENOUS VERSUS STOCK VACCINES.

Autogenous vaccines should be used in preference to stock ones when this is possible, although in staphylococcal and tuberculous lesions the results from a trustworthy stock vaccine are most satisfactory. It is always proper to use a stock vaccine to save time while we are waiting for an autogenous one to be prepared. In infections due to the colon bacillus an autogenous vaccine should always be prepared, as experience has shown that stock vaccines of this microorganism are of little or no use.

In Wright's vaccines the cultures have been devitalized by heat, and suspended in a sterilized physiological salt solution to which 0.5 phenol has been added. The erysipelas vaccine used by the writer is obtained from Dr. George W. Ross, of Toronto, who employs a special technic in its preparation. The microbes which have been therapeutically tested are devitalized by carbolic acid without heat; in this way a vaccine is produced which has twice the potency of one made in the ordinary way (4).

If a stock vaccine is giving satisfactory results it is always proper to continue its use. On the other hand, if no improvement follows the administration of a stock vaccine in a case where a vaccine is clearly indicated, an autogenous suspension should be prepared before abandoning the treatment. One should never lose sight of the possibility of a mixed infection where no benefit results from inoculations in a suitable case.

TUBERCULOUS INFECTIONS.

The methods of therapeutic inoculation have been used most largely and with the greatest prospect of doing good by Wright and others in tuberculosis, more particularly the chronic, strictly localized, and apyral infections, i.e., tuberculous glands, cystitis, ulcers, sinuses, and deposits in the joints and bones.

It has been found that under proper inoculation treatment in the class of cases enumerated above, the symptoms gradually improve, the deposits shrink and disappear, and in the majority of circumstances a successful outcome may be safely predicted as a normal consequence of the treatment. The results at St. Mary's have been most brilliant, and leave no reasonable doubt that the recoveries have been due directly to the effect of the inoculations.

Tuberculous glands under tuberculin inoculation treatment are a triumph for this system of therapeutics. Such cases rarely fail. When inoculations are given as a postoperative treatment in tuberculous lymphnodes we find that less radical surgery is required, recurrence is prevented, and it is not so essential to excise all the infected tissues. Where the inoculations have been resorted to prior to operative treatment, liquefaction and pus formation result more quickly, and removal may be accomplished through a small puncture or a large aspirating needle, care being observed to avoid secondary infection. Continued inoculation treatment results in a complete cure, and the resulting scar is very slight. Tuberculous iritis, cystitis, dermatitis, nephritis, epididymitis, orchitis, peri tonitis, and bone or joint lesions have all yielded to inoculation treatment in the hands of experienced immunizers. Immediate results must not be looked for from inoculation treatment in suitable tuberculous infections, and the patient should be informed at the outset that six to nine months is usually the shortest period required for a cure. The prognosis is better if treatment is begun early.

Pulmonary phthisis is a theme by itself. Inoculations with tubercle vaccine should not be resorted to while active symptoms are present, but the cough and fever should first be allayed and the patient kept quiet and at rest. Such cases should be treated only by an expert immunizer, otherwise serious, if not fatal, harm may be done to the patient. Here the opsonic index is most important. In treating phthisis, as already pointed out, we must always be alive to the possibility of a complicating infection from the streptococcus, pneumococcus, or some other organism, in which case a mixed vaccine would, of course, be necessary to accomplish successful results. In inoculating for phthisis the dose should be very small, because there is a varying amount of spontaneous auto-inoculation taking place from the diseased areas in the lungs, and a negative phase of only a few hours duration might give rise to disastrous activity on the part of the tubercle bacillus.

The absence of scar tissue formation and the resitituto ad integrum, even in very deep and extensive tuberculous ulcers, have been frequently noted after a cure has been effected by inoculation therapy.

The dose may be summarized thus: The minimum effective dose varies from 1/100,000th to 1/15,000th milligram in extensive infections, and from 1/15,000th to 1/50,000th in slight infections; the maximum doses vary from 1/5,000th to 1/3,000th milligram; these latter to be used only in miliary, slight, and localized infections where
lung involvement has been positively excluded. These doses would be much smaller for children. Increase in the doses should be cautious and gradual, with the exercise of extreme care to avoid any clinical symptoms of a negative phase.

**PROPHYLACTIC INOCULATION.**

The inoculation of bacterial vaccines to produce active immunity against various diseases opens up a very large field for investigation and experiment. The result of Wright’s researches positively demonstrates that in certain cases absolute protection may be secured in this way. Preventive doses are, as a rule, much larger than curative doses.

1. Anti-typhoid inoculation. First introduced by Wright, this is now a routine procedure regularly adopted in the armies and navies of both England and the United States. The immunity thus secured is known to last for at least three years. In England only two doses are given: 1,000 millions for the first dose, 2,000 millions for the second, which should follow the first after an interval of ten days. Two inoculations are deemed sufficient (5). In the U. S. Army three inoculations are administered, at intervals of ten days; 500 millions in the first dose and 1,000 millions in the second and third doses. In children and delicate adults the dose would, of course, be smaller. The Widal reaction appears immediately after immunization, and has been known to be still present after a year and a half.

2. Antigonnococcal inoculation. Captain S. R. Douglas has given doses of gonococcus vaccine up to 200 millions to healthy men without marked symptoms. He recommends a commencing dose of about 100 millions and repeating the inoculation in about a week’s time with a larger dose, say 200 millions, providing the first dose did not produce any marked symptoms. This should produce an immunity lasting several weeks. Such prophylactic inoculations would be justifiable where gonorrhoea has been contracted innocently or otherwise by a married person, for the protection of the uninjected partner; in institutions, to prevent the spread of specific vaginitis, which at times is so difficult to control; among sailors before shore leave, and soldiers; and where marriage is contemplated between individuals one of whom has had the disease, and we wish to protect the healthy party to the contract.

3. Anti-influenza inoculation. The writer has repeated given to healthy individuals inoculations of fifty millions without any more discomfort than a slight local reaction. We do not know as yet how much immunity this dose produces or how long it lasts. My practice is to give repeated doses beginning with from ten to fifteen millions and to increase them as long as they do not produce any marked clinical symptoms, at first once a week, and later, when the larger doses are reached once or twice a month. The agglutinins may be measured after the second inoculation. I have endeavored to immunize in this way many patients who during past winters have suffered from severe or recurring attacks of epidemic influenza, its complications and sequelae, and I have been much gratified with the results. All the patients have kept very well and most of them have gained markedly in weight.

**DIFFICULT CASES.**

Occasionally the beginner and the inexperienced inoculator will encounter failures which he cannot understand and which tend to discourage him from the further use of vaccines. Ulcerative endocarditis is often pointed out by the opponents of this system of therapeutics as a disease which should be cured if Wright’s opsonic theory is correct, but which as a matter of fact is not always benefited by inoculations, even where the causative microbe has been isolated in the blood stream. Undoubtedly this disease is quite the hardest disease we are called upon to treat, but the reason is that the actual lesion is not as appears at first sight, in the blood stream, but is situated on a practically bloodless tissue embedded in a mass of unorganized fibrin, so that it is extremely difficult for the immune substances of the serum to reach the active lesion. In this connection it must not be forgotten that a limit is placed to the efficacy of inoculations by the fact that there are definite limits to the responsive power of the patient, and that successful results cannot be obtained unless an efficient lymph stream can be conducted through the focus of infection.

**CONCLUDING REMARKS.**

In inoculating children attention to the technic of the operation is a very important adjunct to success. The hypodermic needle should be small and polished and the point should be sharp. The preparation of the dose should be made in another room where the child cannot see what is going on. A site should be selected where there is plenty of loose tissue; the skin of the abdomen, the buttocks, or the back. If one can avoid scaring or hurting the child at the first inoculation there will be little trouble with subsequent treatments.

The vaccine therapist must have a well equipped general and special laboratory, a vast store of clinical experience, the ability to estimate accurately the opsonic index in doubtful or difficult cases, and the skill necessary to prepare quickly an autogenous vaccine, where one is required. He must also understand how to test therapeutically the various strains of bacteria, as to their immunizing power, so as to determine the doses of the vaccines made up from them.

Properly prepared vaccines will keep indefinitely in a cool, dark place, except the typhoid vaccine, which becomes inert after three months.

In long standing chronic infectious vaccine therapy can be expected to give definite results only after a long succession of inoculations and there is no security against a relapse until the infections have been completely extinguished. Hence the inoculations should be continued even after an apparent cure for a long period, at intervals of several weeks or longer, in order to prevent a recurrence.

The so called “combined” vaccines, manufactured by some of the commercial houses, are made up of a mixture of many different varieties and strains of the more common bacteria. Their use is not to be encouraged any more than “shotgun” prescription writing is to be commended when drugs are used. The idea of the manufacturers in furnishing a combined vaccine is that some one or more of
the strains of the various microorganisms contained in it may apply to the case in question; thus providing a handy "cure all" for a great many pathological conditions, making it possible to dispense with precise bacteriological procedure. Such attempts to make easy the path of the general practitioner is neither scientific nor accurate, and the use of such vaccines in unskilled hands in serious cases might do very great harm.

It is evident that the general practitioner who has given the subject no study had better refrain from attempts at inoculation therapy. The writer can imagine nothing more foolhardy than the haphazard use of biological products by physicians unfamiliar with the theoretical considerations which underlie their administration. Vaccine therapy is a specialty which only the properly qualified should attempt to practise.

It is most important to remember that if sera or vaccines are to be used successfully the earlier they are employed in combating a given infection, the better are the chances of success. Too often the inoculation therapist is called in merely as a last hope, too late to be of any avail. Vaccine inoculations, to be successful, should be administered before the immunizing mechanism of the body has been permanently disarranged by excessive auto-inoculations, or before the limits of the responsive power of the patient have been reached.

Variation in the methods of preparing vaccines materially influences their immediate therapeutic and keeping properties. Hence contributors to medical journals should always mention the methods used in the preparation of an autogenous vaccine or the source from which any stock vaccine used has been obtained.

While up to the present the most brilliant results have been obtained in chronic infections, the indications now are that as we become more expert in interpreting the clinical signs, in determining the correct doses and the intervals between doses, and in making blood tests, in acute infections rather than in chronic ones will vaccine therapy ultimately prove to be of the greatest service.

PREJUDICES AND SUPERSTITIONS MET WITH IN MEDICAL SCHOOL INSPECTION.

By JACOB SOBEL, M. D.,
New York,
Borough Chief, Division of Child Hygiene, Department of Health.

"Parents control the bodies and minds, the hearts and souls of their children not so much by what their ancestors were, as by what they themselves do and think."—Nathan Ophrynein.

As every country has its language, its literature, and its laws, so too, it has its traditions, prejudices, and superstitions; some racial, others religious, which often prove to be serious obstacles in the path of physicians and nurses engaged in municipal health work. In the cosmopolitan city of New York, with its five million people, its seven hundred schools—public and others—and its 825,000 school children, we have several lands in one, for with the swarthy Syrian, the flaxen haired Swede, the confiding loquacious German, the wary and reticent Greek, the suspicious Russian, the doubting Italian, and the Jewish, Irish, Bohemian, Hungarian, Polish, Slavish, Armenian, French, Colored, Japanese, Chinese, and Scandinavian elements, there arises a mass of doubt and hesitancy regarding the laws of health and proper living, which education alone can overcome. It may seem a far reaching statement to make, but the truth is, that in the prevention and treatment of disease among the tenement population in New York city, the physician or health officer must deal not only with the conditions at issue, but, what at times is more difficult, he must meet and combat a fusillade of prejudice, tradition, and superstition, ignorance, distrust, apprehension, indifference, irresponsibility, poverty, and antagonism.
